Abstract

Blood serum samples collected from randomly selected groups of 100 persons inhabiting rural community ‘A’ located in eastern Poland and exposed to floods by the Vistula river, and 98 persons inhabiting rural community ‘B’, also located in eastern Poland, but in the area not exposed to floods were examined by the microscopic agglutination test (MAT) for the presence of antibodies against 18 Leptospira serovars. Positive results showed 3% of serum samples collected from community ‘A’, while the seroprevalence in community ‘B’ was 9.2%, being insignificantly higher than in community ‘A’. For both examined communities (n=198), a significant positive correlation was found between the prevalence and titer of seropositive response and age of examined people (r=0.145, p=0.042). No significant differences were found between the prevalence of positive reactions in males and females (p>0.05). The reactions with 10 serovars of Leptospira (Australis, Autumnalis, Hebdomadis, Hardjo, Sejroe, Zanoni, Bataviae, Bratislava, Canicola and Grippotyphosa), belonging to 3 species (L. interrogans, L. borispeterseni, L. kirschneri), were found in the examined communities. From both communities, of 12 persons demonstrating positive results in MAT, 9 showed reaction with one serovar, 2 with two serovars and 1 with three serovars. The highest titers found during the examination did not exceeded 800. In conclusion, our results suggest that there is only a slight, if any, hazard of an leptospirosis epidemic after the flood that afflicted eastern Poland in the year 2010 and the general epidemiological situation of leptospirosis in eastern Poland. Although there does not seem to be any cause for concern, further research is needed.

Key words

leptospirosis, sero-prevalence, farmers, eastern Poland

INTRODUCTION

Leptospires are thin, helical bacteria classified currently into at least 13 pathogenic species, comprising in turn more than 260 serovars, and 6 saprophytic species, with more than 60 serovars [1, 2]. Although this classification is dynamic, it is expected that additional new species also exist [1]. Leptospires are capable of surviving in a wide range of moist environmental conditions, including soil, mud, ground water, streams, rivers and lakes [3]; however, the main niche for their maintenance are warm-blooded organisms, mainly mammals. Leptospires survive usually in the renal tubules of rodents and many other wild and domestic animals [1, 2, 4]. Humans become infected most commonly through occupational, recreational, or domestic contact of skin with the urine of infected animals, either directly or via contaminated water or soil [1, 5].

Leptospirosis is regarded as the most widespread zoonosis in the world that represents a re-emerging health problem because of increasing the incidence among humans and domestic animals [1, 6, 7, 8, 9]. Depending on the serovar, the immune status of the host and many other known and unknown factors, the disease can run as a mild, flu-like illness or a severe infection capable causing serious multiorgan or systemic disorders leading to death. Despite this, the disease is severely neglected and the estimated incidence of about half a million severe human cases annually is probably an underestimation [10]. Leptospira spp. present an occupational risk to agricultural workers, slaughterhouse workers, sewage workers, veterinarians and other professions [5, 11]. The mechanisms of pathogenesis of Leptospira are largely unknown [8]. With global climate change, extreme weather events such as cyclones and floods are expected to occur with increasing frequency and greater intensity and may potentially result in an upsurge in the disease incidence, as well as the magnitude of leptospirosis outbreaks [12]. The natural foci of leptospirosis may occur in swampy areas and could be described as ‘marsh fever’ [13, 14].

Leptosporal infection in humans may be symptomless and the only proof of such infection are specific anti-Leptospira antibodies. Thus, the serological response rate of the examined population to Leptospira antigen may be regarded as an indicator of prior contact with these bacteria and the degree of exposure. Reported response rates in agricultural workers living in the countries located in the tropical climate
zone (Tanzania, Nigeria, Somalia, India) are within the range of 19.4-62.5% [15, 16, 17, 18], whereas the analogous rates in similar workers living in the temperate climate zone (The Netherlands, USA, Northern Ireland, Italy) are usually lower, ranging between 0.5-23.5% [19, 20, 21, 22, 23, 24].

The aim of this study was to investigate seroprevalence of *Leptospira* spp. among adult farmers living in two rural communities of the Lublin Province in eastern Poland. Community 'A' is situated on the Vistula river, in the western part of the province, an area often exposed to the consequences of raised levels of the river (wet soil, inundations), and in the summer of 2010 was afflicted by two huge floods. By contrast, community 'B' is situated in the central part of the province and does not experience floods.

**MATERIALS AND METHODS**

**Examined population.** Blood serum samples collected from 100 randomly selected persons (27 males and 73 females) inhabiting the rural community 'A', exposed to floods, and serum samples from 98 persons (27 males and 71 females) inhabiting the rural community 'B' not exposed to floods, were examined during the study. The mean age of the investigated group for community 'A' (x±S.D.) was 51.1 ± 13.4 yrs (range 18-79 yrs), while for community 'B' it was 54.1 ± 14.7 yrs (range 18-85 yrs). Collected serum samples were examined by the microscopic agglutination test (MAT) with live antigens.

**Antigens.** Cultures of reference strains of *Leptospira interrogans* serovars: Australis, Autumnalis, Bataviae, Bratislava, Canicola, Hardjo, Hebdomadis, Icterohaemorrhagiae, Pomona, Zoanoni, – *L. borreliari* serovars: Ballum, Poi, Serjoe, Tarassovi, – *L. kirschneri* serovars: Cynopteri, Grippotyphosa, – *L. weili* serovar Celledoni, – and *L. biflexa* serovar Patoc kept in the Department of Swine Diseases of the National Veterinary Research Institute in Pulawy were used for preparation of MAT. The strains were obtained from FAO/WHO Reference Laboratory for Leptospirosis of the Royal Tropical Institute in Amsterdam. Leptospires were cultivated in EMJH (Ellinghausen McCullough Johnson and Harris) liquid medium at 30°C in aerobic conditions. The strains were subcultured every 7 days.

**Microscopic agglutination test.** This test was carried out according to the OIE Manual of Standards for Diagnostic Tests and Vaccines [25], as described previously [26]. The serum samples were mixed with an equal volume of each of the *Leptospira* serovars. Serum dilution (including added antigen) used during preliminary examination was 1:100. For samples reacting in the preliminary examination with one or more serovars, series of twofold dilutions were prepared to titre the end point – 50% agglutination. The samples with titres ≥100 were recognized as positive.

**Statistical analysis.** The data were analysed by Student’s t-test and Pearson’s test for correlation, with the use of STATISTICA for Windows v. 5.0 package (StatSoft Inc., Tulsa, Oklahoma, USA).

**RESULTS**

The results are summarized in Table 1. In the group of persons from community 'A', 3% of serum samples showed the presence of anti-*Leptospira* antibodies. In community 'B', not affected by flood, the seroprevalence was 9.2%, being insignificantly higher than in community 'A' (p=0.0764).

Reactions with 10 serovars of *Leptospira* spp. belonging to 3 species (*L. interrogans*, *L. borreliari*, *L. kirschneri*) were found in the examined communities. From both communities, a total of 12 persons who presented positive results in MAT, 9 of them showed positive reactions with one serovar, 2 with two serovars and 1 with three serovars (Tab. 1). Altogether, there were indicated 2 serum samples reacting with serovar Australis and 2 with serovar Zoanoni, 5 samples, each reacting with one of following serovars: Bataviae, Bratislava, Canicola, Grippotyphosa, Hebdomadis, 1 serum reacting with serovars Sejroe and Hardjo, 1 reacting with serovars Hebdomadis and Autumnalis and 1 showing reactions with serovars Hebdomadis, Hardjo and Sejroe. Among the positive samples, 4 sera presented titre 100, 4 showed titre 200, 3 demonstrated titre 400 and 1 – titre 800.

**DISCUSSION**

In Poland, the most important endemic area of leptospirosis is Lower Silesia, an area where epidemics of 'marsh fever', often associated with floods, propagation of rodents and/or performing of agricultural works, have been described since the 19th century up to the second half of the 20th century [13, 14, 27, 28, 29]. In the southern part of the Lublin Province, epidemics of leptospiral 'marsh fever' were noted in the years
1954-1955 [14]. In 1955, a scientific expedition consisting of experts from medicine, veterinary medicine and biology was organized to elucidate the etiology, pathogenesis and environmental aspects of the epidemic [30, 31]. Samples for serological and microbiological investigations were collected from over 400 hospitalized persons. Additionally, over 2,500 small mammals were caught in area affected by the epidemic [32, 33]. The animals were subjected to serological and microbiological examination for presence of *Leptospira* spp., the results of which indicated serovar Grippotyphosa as the most widespread etiological agent of the disease. The second serovar often found in humans and small mammals was Sejroe.

In the years 1955 and 1956, a total of 608 serum samples were collected from inhabitants of the epidemic region who were ill or suspected of being ill with leptospirosis. Antibodies for 11 serovars of *Leptospira* were found in 60.9% of these samples. Almost 69% of positive samples reacted with serovar Grippotyphosa and 15% with serovar Sejroe [34]. Serological findings of 4,322 domestic animals (cattle, horses, pigs, sheep, hens, geese, ducks) from this region, also carried out in 1955-1956 indicated 13.3% of positive results. Among positive samples, 31% reacted with serovar Grippotyphosa, 28% with serovar Icterohaemorrhagiae, 23.4% with serovar Bovis, and the remaining 17.6% with serovars: Pomona, Canicola, Sejroe, Mittis, Australis, and Saxkoebing. In 1957-1958, only a few cases of human leptospirosis were noted in the southern part of Lublin Province [33]. It was not until twenty years later that a group of 10 leptospirosis cases were described in the eastern part of the province [35]. No extensive epidemics of leptospirosis have occurred in Poland since the 1970s, not (western Poland) 1.2% of seropositive reactions to *Leptospira* spp., the results of which indicated serovar Grippotyphosa in the farmers living in the Wielkopolskie Province et al. [36] who found 11% of seropositive reactions to *Leptospira* in the farmers living in the north-central part of Lublin Province. Our results are also lower compared to those reported by Krawczyk [38] who found 13.8% of seropositive reactions among the rural inhabitants of Kujawsko-Pomorskie Province exposed to infected animals, and 1.5% among those without such contact. Compared to similar studies performed in Europe, the results of the presented study are higher compared to those obtained in the Netherlands by Elbers et al. [19] (0.5%), and lower compared to those obtained in Northern Ireland by Stanford et al. [22] (8.1%), and in Italy by Nuti et al. [23] (10-12%) and Fenga et al. [24] (23.5%).

In conclusion, the results of the presented study suggest that there is only a slight, if any, hazard of a leptospirosis epidemic after the flood that affected eastern Poland in 2010. However, although the general epidemiological situation of leptospirosis in eastern Poland does not seem of great concern, further research is still needed.
