Abstract

Music now plays an increasing role in several disparate areas. Music therapy appears to affect physiological phenomena such as blood pressure, heart beat, respiration, and mydriasis as well as emotional aspects such as mood and feelings. It is used in the rehabilitation of patients with dementia, Parkinson’s disease, fibromyalgia, stroke, aphasia and visual rehabilitation. Music in the patient with dementia produced significantly higher levels of interest and pleasure than the baseline condition. In accordance with the clinical literature, it may be argued that the Music Therapy-induced improvement in bradykinesia could be due to the effect of external rhythmic cues, which, acting as a timekeeper, may stabilize the internal rhythm formation in patients with Parkinson’s disease. In fibromyalgia was to investigate the effects of sleep and touch therapy accompanied by music and aromatherapy on the symptoms of fibromyalgia and depression. In stroke rehabilitation, elements of music have previously been used as a part of physiotherapy and speech therapy to enhance the recovery of motor and speech functions. One of the few accepted treatments for severe, nonfluent aphasia is Melodic Intonation Therapy (MIT), a treatment that uses the musical elements of speech (melody & rhythm) to improve expressive language by capitalizing on preserved function (singing) and engaging language-capable regions in the undamaged right hemisphere. Mozart’s Sonata for Two Pianos was used to visual rehabilitation. The following paper is based on information obtained from the literature review on the use of music therapy in rehabilitation. Conclusion: The use of music therapy in the rehabilitation is huge, but little appreciated. Music therapy is a method of cost-effective, non-invasive where it no reported its side effects. There are small number of studies and publications on the use of music as a form of rehabilitation.

Key words

music therapy, rehabilitation, disease

INTRODUCTION

Music now plays an increasing role in several disparate areas. Music can reduce stress, improve athletic performance, improve motor function in neurologically impaired patients with stroke or Parkinsonism [1]. Moreover, patients who listened to music also experienced less depressed and, to a lesser extent, confused mood after the intervention than patients who received no listening material. Since the patient groups did not differ in demographic and clinical variables at the baseline or in antidepressant medication and rehabilitation received during the intervention, and since any non-specific effects of therapeutic attention were controlled for, these differences observed in cognitive recovery can be directly attributed to the effect of listening to music [2]. Music therapy appears to affect physiological phenomena such as blood pressure, heart beat, respiration, and mydriasis as well as emotional aspects such as mood and feelings [3, 4, 5]. Clinical studies in adults also demonstrated correlations between the physiological and emotional stimulation effects of music [4, 5]. Music has been used as a form of therapy for many different diseases and, unless hearing is totally affected, may indeed be experienced and appreciated by even the most severely physically or cognitively impaired subjects [6]. Music Therapy has been widely used in the rehabilitation of handicapped children, providing one of the few ways in which these subjects can attain self-expression [7]. In addition, Music Therapy is recommended in geriatric care to improve the social, psychological, intellectual, and cognitive performance of older people [8, 9]. Depressed older adults, in particular, can experience the effects of passive Music Therapy [10, 11]. Finally, anecdotal evidence and clinical studies show that Music Therapy improves the cognitive functions and quality of life of patients with Alzheimer’s disease [12, 13, 14, 15].

Dementia. According to the World Health Organization report published in 2012, the estimated number of people living with dementia exceeds 35.6 million worldwide (Alzheimer’s Disease International, 2009). This number is predicted to double by 2030, and more than triple by 2050 (Alzheimer’s Disease International, 2009). Our results concerning music are of note, as we found that music produced low levels of interest and pleasure in comparison to other stimuli [16]. To our knowledge, there are no other studies of music that utilize pleasure as a specific outcome measure in this population. Several studies have linked music to a decrease in agitation and/or apathy in persons with dementia [17, 18, 19], and an increase in positive social behaviors [20]. Gotell et al. found that music increased awareness of and interest in their environment in persons with dementia [21]. Our results agree with those findings in that music produced significantly higher levels of interest and pleasure than the baseline condition [22].

Alzheimer’s disease (AD), the most common form of dementia, is characterized by a general, progressive decline in cognitive function that typically presents first as impaired episodic memory. The main goal of the present study was to determine the extent to which music can be used to enhance memory for associated verbal information in patients with AD and healthy older adults. The results confirmed our
hypothesis that patients with AD performed better on a task of recognition memory for the lyrics of songs when those lyrics were accompanied at encoding by a sung recording than when they were accompanied by a spoken recording. Musical mnemonics provide an intricate neurophysiologic template for the mapping of verbal information in temporal and tonal space, and this template may be used during retrieval to aid in lyric recognition or recall. For healthy older adults with intact cortical memory circuits, it is possible that the relatively simple nature of the recognition task in the current paradigm does not produce a need to recruit from these areas of the brain not typically used for recognition memory, and so results in no difference between the sung and spoken conditions. In other words, there may be no need to rely on the holistic musical memory “backup” at the part of the performance scale where control subjects scored [23]. It is also possible that attentional deficits in patients with AD [24] and the ability of music to moderate these deficits by heightening arousal [25], account for the effect of condition in the patient group [23].

**Parkinson’s Disease.** Parkinson’s Disease (PD) is a common degenerative disease dominated by a disorder of movement, consisting of bradykinesia (slowness of movement), hypokinesia (reduced movements), tremor, rigidity, and postural and gait abnormalities; mood changes are also a major component of PD [26]. This study is the first to assess objectively the effect of a systematic program of active Music Therapy on standardized measures of PD severity using a prospective, single-blinded design. Moreover, this randomized, controlled clinical study compared the efficacy of Music Therapy and Physical Therapy to highlight any eventual difference between the two methods in their effect on both physical and emotional functions. Our results demonstrate improvements in motor abilities and emotional status related to active Music Therapy. The improvement in motor performance was related mainly to changes in bradykinesia. Although the Music Therapy-related motor response seemed to decline after each session, a trend of improvement was observed in the Music Therapy group in the overall evaluation. Improvement in emotional functions was found both after each Music Therapy session and throughout the entire study period, but when measured 2 months after completion of Music Therapy, the values returned to baseline levels. Significant improvements in ADL and quality of life were also documented in patients undergoing Music Therapy. Physical Therapy, meanwhile, led to a clear improvement in rigidity but did not induce any major changes in other variables [27]. In accordance with the clinical literature, it may be argued that the Music Therapy-induced improvement in bradykinesia could be due to the effect of external rhythmic cues, which, acting as a timekeeper, may stabilize the internal rhythm formation process in patients with PD [27, 28, 29, 30]. This motor power of rhythm may be especially strong in various forms of motor and impulse disorder—and music can indeed be therapeutic here. Thus, patients with parkinsonism, in whom movements tend to be incontinently fast or slow or sometimes frozen, may overcome these disorders of timing when they are exposed to the regular tempo and rhythm of music [31].

**Fibromyalgia.** Fibromyalgia is a chronic disease characterized by sensitive points on the body that manifest common musculoskeletal pains, fatigue, and low pain threshold. Although there is no clear-cut data about the prevalence and incidence of FMS in the world, prevalence is generally between 6% and 20% [32, 33]. The aim of the study Demirag et all [33] was to investigate the effects of sleep and touch therapy accompanied by music and aromatherapy on the symptoms of fibromyalgia and depression, and the findings are as follows (These results support the study hypotheses): The TMA(touch therapy accompanied by music and aromatherapy) intervention reduced FMS symptoms in patients, and the change is statistically significant. The SMA (sleep accompanied by music and aromatherapy) intervention reduced FMS symptoms in patients, and the change is statistically significant. The education given to the patients in both the TMA and SMA groups during the intervention was effective in decreasing the symptoms [33].

**Visual rehabilitation.** Salvatore et all in publication describes a 74-year-old patient with open angle glaucoma in both eyes and macular pucker in the right eye (RE) underwent visual rehabilitation with acoustic biofeedback by means of the MAIA™ Vision Training Module (Centervue, Padova, Italy) 10 minutes each eye once a week for 5 weeks. The patient was asked to move his eyes according to a sound which changed into Mozart’s Sonata for Two Pianos when the patient locked the fixation target. This is the first time that Mozart music has been applied to a visual rehabilitation, and the results are worthy of attention. Music could enhance synaptic plasticity in the brain and affect neural learning and fixation training. By means of MAIA, we can improve the visual performance in patients with macular pucker to postpone the surgical time and assure the patient a better quality of life [34].

**Stroke.** During the first weeks and months of recovery after a stroke, the brain can undergo dramatic plastic changes [35, 36] that can be further enhanced by stimulation provided by the environment. In stroke rehabilitation, elements of music have previously been used as a part of physiotherapy [37] and speech therapy [38] to enhance the recovery of motor and speech functions. In addition, nonverbal auditory stimuli have been shown to temporarily ameliorate left visual neglect after stroke [39]. However, the knowledge about the long-term effects of everyday music listening itself on the recovery of cognitive and emotional functions after stroke is very limited [2]. Musical training has extensive effects on the brain. One aspect that may be relevant for stroke rehabilitation is that musicians have enhanced subcortical auditory and audiovisual processing of speech and music [40, 41, 42]. In the study, authors have observed significant motor gains accompanied by plastic changes in chronic stroke patients who were tested before and after 20 sessions of music supported therapy (MST). Of note, they found increased motor cortex excitability in the patients’ affected hemisphere after training, an association between changes in the motor cortex representation on the injured hemisphere and improved performance of diadochokineti movements with the affected upper limb. These results suggest that MST can drive task-dependent cortical reorganization in stroke patients in the chronic stage [43].

Kim et all in their publication describe in conclusion: ‘Music therapy has a positive effect on mood in post-stroke patients and may be beneficial for mood improvement with stroke’. These results are encouraging, but further studies
are needed in this field. In their investigation psychological status was evaluated with the Beck Anxiety Inventory (BAI) and Beck Depression Inventory (BDI) before and after music therapy. Satisfaction with music therapy was evaluated by a questionnaire. Results: BAI and BDI scores showed a greater decrease in the music group than the control group after music therapy, but only the decrease of BDI scores were statistically significant (p=0.048). Music therapy satisfaction in patients and caregivers was affirmative [5].

**Aphasia.** According to the National Institutes for Health (NINDS Aphasia Information Page: NINDS, 2008), approximately 1 in 272 Americans suffer from aphasia, a disorder characterized by the loss of ability to produce and/or comprehend language. Despite its prevalence, the neural processes that underlie recovery remain largely unknown and thus, have not been specifically targeted by aphasia therapies. One of the few accepted treatments for severe, nonfluent aphasia is Melodic Intonation Therapy (MIT), a treatment that uses the musical elements of speech (melody & rhythm) to improve expressive language by capitalizing on preserved function (singing) and engaging language-capable regions in the undamaged right hemisphere. In speech, phonemes occur so quickly it is difficult for severely aphasic and/or apraxic patients to process auditory feedback in time to self-correct. However, when words are sung, phonemes are isolated and thus, can be heard distinctly while still connected to the word. In addition, sustained vowel sounds provide time to “think ahead” about the next sound, make internal comparisons to the target, and self-correct when sounds produced begin to go awry [49]. Recovery from aphasia can happen in two ways: either through the recruitment of perilesional brain regions in the affected hemisphere, with variable recruitment of right-hemispheric regions if the lesion is small, or through the recruitment of homologous language and speech-motor regions in the unaffected hemisphere if the lesion of the affected hemisphere is extensive. Treatment-associated neural changes in patients undergoing MIT indicate that the unique engagement of right-hemispheric structures (e.g., the superior temporal lobe, primary sensorimotor, premotor and inferior frontal gyrus regions) and changes in the connections across these brain regions may be responsible for its therapeutic effect [50].

**CONCLUSIONS**

The use of music therapy in the rehabilitation is huge, but little appreciated. Music therapy is a method of cost-effective, non-invasive where it no reported its side effects. There are small number of studies and publications on the use of music as a form of rehabilitation.
