### Ballistic Behaviour of PACVD-Modified Textiles

**DOI:** 10.5604/01.3001.0012.7512

**Abstract**

A comprehensive study was performed using the Plasma Assisted Chemical Vapour Deposition (PACVD) modification of ultrahigh molecular weight polyethylene (UHMWPE) fibrous composites and p-aramid fabrics with the deposition of fluoroo- or silane-like-polymer onto their surface. Research on the resistance to fragments was performed on the basis of our own testing procedure elaborated on the basis of the STANAG 2920 Ballistic Test Method For Personal Armour Materials And Combat Clothing, revision 2. The model insert systems made of the modified or unmodified unwoven sheets of UHMWPE fibres exhibited significantly different trends of changes in fragment-proofness when the temperature together with humidity were applied as the ageing factors. In the inserts made of modified unwoven sheets, an increase in the V50 value was observed, while the V50 of the inserts made of unmodified sheets decreased along with the extension of the accelerated ageing process. Modification with low-temperature plasma in the presence of vapours of low-molecular fluorine- or silane-genic substrates altered the properties of the fabrics and unwoven sheets. PACVD modification allows to prevent the destructive influence of humidity during the ageing process.

**Key words:** PACVD-modified textiles, ballistic compositions, accelerated ageing.

---

**Introduction**

The stability of the ballistic protection’s performance during use and storage is a main factor affecting its safety. The application of a physical barrier (semi-permeable textile covers) of ballistic inserts allows to partially limit the risk of degradation of the ballistic materials accelerated by humidity (external – rain; internal – sweat) and/or temperature [1,2]. The possibility of the direct prevention of ballistic textiles and fibrous-originated composites, allowing prolongation of the safe use of ballistic protectors and to reduce the cost of manufacture with limitation of environmentally unfriendly wastes was the main aspects of [3,4].

The effect of accelerated ageing on the main physico-mechanical and structural properties was tested using PACVD-modified soft UHMWPE fibrous composites and p-aramid woven fabric with the deposition of silane-like- or fluoropolymer onto surfaces. The accelerated ageing of PACVD-modified textiles confirmed the significant effect of the surface-deposited polymer on the main performance of the ballistic textile and a protection effect against the ageing factors, varying in relation to the type of accelerated ageing factor used.

Moreover the accelerated ageing of PACVD-modified p-aramid fabrics by the deposition of fluoropolymer indicated the initiation of superhydrophobic behaviour, significantly supporting resistance against the degradation following lost mechanical strength [5].

PACVD modification of a textile surface should not affect the ballistic resistance and ought to prevent the stability of the above-mentioned functionality during long-term use and storage. Taking into account the above, the aim of the study was to evaluate:

1. the effect of PACVD modification of both types of ballistic textiles: p-aramid woven fabric and UHMWPE fibrous composites on the ballistic behaviour shown by the bullet- and fragment proofness, and
2. the stability of the ballistic behaviour of the PACVD-modified materials during simulated ageing using temperature or temperature and humidity.

**Materials**

**Textile materials**

Two types of the ballistic textiles were used in the research:

- Woven fabric Style 363/120 (SAATI S.P.A., Italy), made of p-aramid yarns;
- Dyneema® SB51 UHMWPE fibrous composite (DSM/The Netherlands) [6].

In order to perform tests of ballistic properties and accelerated ageing during the optimisation research, ballistic insert model systems were designed, which constituted ballistic packets consisting of:

- 38 layers of p-aramid woven fabric Style 363/120 (PACVD-modified or unmodified);
- 22 unwoven sheets of UHMWPE fibres (PACVD-modified or unmodified).

After the process of accelerated ageing, the insert model systems underwent further research for verification of the result stability of the process of modification with low-temperature plasma in the presence of vapours of tetradecafluorohexane (TDFH) or hexamethyldisiloxane (HMDSO) regarding their ballistic properties.

**Substrates for PACVD (Plasma Assisted Chemical Vapour Deposition)**

Dyneema SB51 was PACVD-modified using hexamethyldisiloxane (C\(_3\)H\(_8\)OSi\(_3\)); HMDSO) from Sigma Aldrich, whereas for surface PACVD modification of p-aramid woven fabric, tetradecafluorohexane; C\(_6\)F\(_{22}\); (TDFH), 99%, from Tokyo Chemical Industry/Japan was used.

**Methods**

**Surface modification of Dyneema® SB51 by PACVD**

The modification of Dyneema® SB51 in glow discharges was performed in a commercial plasma jet – CD 400PLC ROLL CASSETTE (EUROPLASMA/ Belgium) according to [7] using the following process parameters:

- for PACVD-modified Dyneema® SB51: polymerisation in a stream of HMDSO at a flow rate of 0.032 g min\(^{-1}\) with a power of 100 W applied to the electrodes, for a time of 3 min.
The resistance to bullets was tested on the basis of the PN-V-87000:2011 Standard, with the use of a 7,62 x 25 TT bullet with a lead core and bi-metallic jacket of a mass of 5.5 ± 0.1g, at a velocity of 420 ± 15 m/s (class K2).

The research was performed on samples of 250 x 250 mm, subjected to thermo-stating at a temperature of 20 ± 3 °C and relative humidity of air of 65 ± 5% for a time period no shorter than 5 hours. Moreover the research included assessment of the number of penetrated layers of the insert model system as well as of the depth of the momentary, dynamic deflection of an insert by measuring the depth of deformation of the ballistic base behind the insert.

### Results and discussion

#### Research on the resistance to fragments

Every test was performed on 2 insert model systems, with the calculation of V50 and Δ for each sample, and consequent calculation of the mean of aggregate results of 2 insert model systems.

The periods of accelerated ageing were chosen based on the experiments of previously completed research projects involving the accelerated ageing of ballistic materials, which concluded that the period between 28 and 42 days, which corresponds to 3 years of ageing of ballistic materials under real conditions, is critical concerning the changes in their properties.

#### Research on the resistance to bullets

It was found that the greatest changes in V50 occurred after the first 28 days of accelerated ageing of the ballistic model systems, which corresponds to 2 years of ageing under real conditions. The trend of changes was similar for both ballistic model systems of modified and unmodified fabrics.

The introduction of an additional ageing factor – humidity, made the changes observed more dynamic with a similar trend to that of the inserts aged with the temperature factor only. The largest decrease in V50 occurred in the inserts made of unmodified fabrics (ca. 11% compared to the initial value after 42 days of accelerated ageing). In the inserts with modified fabric, the decrease was lower by half (ca. 5% compared to the initial value).

#### Model insert systems made of modified or unmodified unwoven sheets of UHMWPE fibres

A similar trend of V50 changes to that of the model insert systems made of p-aramid fabrics was observed in the inserts of modified and unmodified unwoven sheets, provided they were aged with the temperature agent. No remarkable differences in V50 were observed in dependence on neither the time of accelerated ageing, nor on the modifications of the sheet’s surface.

In the process of ageing where the temperature together with humidity were the ageing factors, a remarkable reduction in V50 was observed in the course of the accelerated ageing of the model insert systems comprising unmodified unwoven sheets. In the case of the model in-
The research included assessing two additional parameters: the number of the model insert system layers penetrated with the bullet and the depth of the temporary, dynamic deflection of the insert by measuring the depth of deformation of the ballistic base behind the system tested. In the case of full piercing of the model system, the total number of layers was recorded as the number of penetrated layers, and the maximum permissible value of 40 mm was recorded as the observed deflection.

**Model insert systems of unmodified or modified p-aramid fabrics**

The dependence of the mean value of the number of layers penetrated by a bullet in the model insert systems of modified and unmodified p-aramid fabrics assessed, on the time of the accelerated ageing process where temperature was the only ageing factor is presented in Figure 6.

In the inserts developed with the modified systems, a decrease was observed in the mean value of the number of fabric layers penetrated by the bullet, unlike the insert systems made of unmodified fabrics. However, the changes above were insignificant in the light of statistical analysis.
The dependence of the mean number of the layers penetrated by a bullet in the model insert systems of modified (A/M) and unmodified (A/N) p-aramid fabrics assessed on the time of the accelerated ageing process where the temperature was the only ageing factor.

Figure 9. Dependence of the base deformation on the time of the accelerated ageing process in the model insert systems of modified (A/M) and unmodified (A/N) p-aramid fabrics assessed where the temperature with humidity were the ageing factors.

Figure 10. Dependence of mean number of the layers penetrated with a bullet in assessed model insert systems with the modified (D/M) an modified (D/N) unwoven sheets on the time of accelerated ageing process where the temperature was the only ageing factor.

Figure 11. Dependence of the mean value of base deformation in the model insert systems made of modified (D/M) and unmodified (D/N) unwoven sheets assessed on the time of the accelerated ageing process where the temperature was the only ageing factor.
Figure 7 presents the dependence of ballistic base deformation for the insert model systems of modified and unmodified p-aramid fabrics assessed on the time of the accelerated ageing process where the temperature was the only ageing factor. The model insert systems made of fabrics subjected to modification were characterised with a slightly bigger mean deflection of the ballistic base compared to the unmodified systems, which may be linked to the decrease in the multidirectional strength (perforation) of the single layers observed during the mechanical tests (this might be due to loosening of the fabric structure in the modification process during preparation of samples for processing). Along with prolongation of the accelerated aging process, the average depth of the deformation decreased, at a lower rate in the systems with modified fabrics.

In the case of prolongation of the accelerated ageing process where the temperature together with humidity were the ageing factors, a decrease was observed in the mean number of penetrated layers in the model insert systems, both in samples made of unmodified fabrics and in the modified ones (Figure 8). The differences between the mean numbers of layers penetrated in the inserts made of the modified and unmodified fabrics were statistically insignificant.

Figure 9 presents the dependence of the base deflection for the model insert systems of modified and unmodified p-aramid fabrics assessed on the time of the accelerated ageing process where the temperature together with humidity were the ageing factors.

A trend similar to that observed when the ageing factor was the temperature alone (decrease in the average deformation depth of the base during aging) was observed in accelerated ageing with the temperature and humidity together.

As in ageing with the temperature factor, mean values of the depth of base deformation were lower in the model insert systems made of unmodified p-aramid fabrics.

Model insert systems of unmodified or modified unwoven sheets of UHMWPE fibres
For the model insert systems of the modified and unmodified unwoven sheets, the dependence of the mean number of layers penetrated by the bullet on the time of the accelerated ageing process where the temperature was the only ageing factor, is presented in Figure 10.

Along with the length of accelerated ageing, the average number of penetrated layers increased in both systems of modified and unmodified sheets. Differences in the parameter between the systems assessed were statistically insignificant.

It should be noted that after the longest time of the accelerated ageing process, full piercing was observed in the model insert system of unmodified sheets.

Figure 11 presents the dependence of the mean value of deformation of the model insert systems made of modified and unmodified unwoven sheets assessed on the time of the accelerated ageing process where the temperature was the only ageing factor.

Research on the accelerated ageing of the insert systems where the only ageing factor was the temperature did not discover significant statistical differences in the mean value of the base deformation.

Under the testing conditions no significant changes in the mean number of perforated layers of unwoven sheets, both modified and unmodified, were observed during the accelerated ageing process where the temperature with humidity were the ageing factors (Figure 12).

When assessing the depth of base deformation, an insignificant decrease in its mean value was observed for the model insert systems made of unmodified sheets (Figure 13). When assessing the inserts made of modified unwoven sheets, no significant statistical changes were observed in the above parameter.

Conclusions
As part of works performed for confirmation of the stability of functional features, tests were executed to verify the ballistic resistance (fragment-proofness and bullet-proofness) of optimised model insert systems (consisting of textile materials, unmodified or modified) before and after the process of accelerated ageing.
Regarding the model insert systems made of p-aramid fabric subjected to modification or not, after the process of accelerated ageing with the temperature factor, similar change trends were discovered in the V50 – the parameter that determines the fragment-proofness. Significant alteration in the volume of the V50 parameter was identified after the first 28 days of accelerated ageing of ballistic model systems consisting in modified and unmodified p-aramid woven fabric systems with p-aramid woven fabrics.

In another research variant where humidity was applied as an ageing factor in addition to the temperature, a distinct decrease in V50 (approx. 11% as compared to the initial value of V50 after 42 days of accelerated ageing) was discovered during accelerated ageing of the model insert systems produced of unmodified fabrics, which was lower by half (by approx. 5% as compared to the initial value) in the inserts designed with PACVD modified woven fabric.

The research confirms the stability of the material’s functional parameters gained in the process of modification with low-temperature plasma at a level sufficient to observe a decrease in the dynamics of changes in the bullet-proofness in the inserts of modified fabrics.

The model insert systems made of modified or unmodified unwoven sheets of UHMWPE fibres exhibited a significantly different trend of changes in fragment-proofness when the temperature together with humidity were applied as the ageing factors. In the inserts made of modified unwoven sheets, an increase in the V50 value was observed, while the V50 of the inserts made of unmodified sheets decreased along with the extension of the accelerated ageing process.

Tests of the bullet-proofness according to the K2 class (of the PN-V-87000:2011 standard) did not show – it is worth emphasizing – any case of full piercing of the model insert systems made of textile materials subjected to low-temperature plasma modification in the presence of vapours of TDFH or HMDSO.

Among the insert systems made of unmodified materials based on either p-aramid fabrics or unwoven sheets of UHMWPE fibres, full penetration (piercing) with a projectile was observed in the samples after 42 days of ageing where the only aging factor was the temperature.

During the research on the number of perforated layers of the model insert systems subjected to the process of accelerated ageing, no statistically significant changes were observed in the inserts made of p-aramid fabrics, either modified or not. The same similarity was observed when assessing the deformation depth upon shooting. In the inserts made of unwoven sheets subjected to modification, the process of accelerated ageing conducted with either temperature alone or temperature with humidity did not significantly change the number of perforated layers nor the deformation depth, as compared to the results of tests performed on the model insert systems made of unmodified sheets.

In conclusion, it should be emphasized that modification with low-temperature plasma in the presence of vapours of low-molecular fluorine- or silane-genic substrates altered the properties of the fabrics and unwoven sheets. The above-observed phenomenon i.e. humidity is a more critical factor influenced the ballistic behaviour of the p-aramid woven fabric. Moreover PACVD modification allows to prevent the destructive influence of humidity during the ageing process.
