TESTS OF ROTARY MACHINES VIBRATIONS IN STEADY AND UNSTEADY STATES ON THE BASIS OF LARGE DIAMETER CENTRIFUGAL FANS

BADANIA DRGAŃ MASZYN WIRNIKOWYCH W STANACH USTALONYCH ORAZ NIEUSTALONYCH NA PRZYKŁADZIE WENTYLATORÓW PROMIENIOWYCH DUŻYCH ŚREDNIC

Problem występowania stanów nieustalonych maszyn obrotowych jest powszechnie spotykany. Pojawia się on głównie podczas rozruchu i wywołuje „przechodzenie” przez prędkość krytyczną, która wzbudza drgania obiektu w bardzo szerokim zakresie. Ponadto problemy z drganiami maszyn obrotowych wywoływane są przez takie czynniki jak niewyważenie, niewyosiowanie, defekty łożysk i wiele innych. W pracy przedstawiono wyniki badań drgań zarówno w stanach ustalonych jak i nieustalonych przykładowych wentylatorów promieniowych. Za pomocą widm STFT przeanalizowano zarejestrowane przebiegi drgań niestantycznych. Dzięki temu możliwe było zidentyfikowanie głównych parametrów mających wpływ na poziom drgań podczas rozruchu oraz pracy normalnej. Badania przeprowadzono na czterech obiektach, co umożliwiło dodatkowe porównanie i wyciągnięcie wniosków odnośnie parametrów eksploatacyjnych całego układu przepływowego.

Słowa kluczowe: maszyny obrotowe, stany nieustalone, drgania.

1. Introduction

Vibrations in steady and unsteady states [18] occur in almost all cases of rotary machines operation. In the first case, vibrations occur during the nominal operation of the machine and, generally, if the technical condition of the machine is good, do not constitute a significant operational problem. The other type of vibrations occurs during the start-up and braking of a supercritical machine. If the rotary machine is set in motion properly and under control, vibrations occurring during the operation are not a significant risk. It is important to smoothly and quickly “pass through” critical velocities of the rotary machine. The critical velocity matching resonance frequency might become a cause of damage of the machine, if the start-up is not performed properly. Rotation of the elements with the critical velocity provides high energy of excitation in wide spectrum. This causes resonance vibrations of the system. It has to be noted that the critical velocity of the rotor, often matching the frequency of its natural vibrations, is not the only resonance area in which the fan may operate. In the case of more complex machines, the frequency of natural vibrations of particular elements, e.g. a casing has to be taken into account. Additionally, in the case of fan rotors, it has to be remembered that the excitation frequency equals the rotary frequency of the shaft but also the blade passing frequency, which is the product of the number of blades and a rotary velocity of the shaft [16]. Moreover, numerous flow effects cause dangerous vibrations of fan elements in other frequency ranges [7, 8, 25].

The level of excitation energy is also influenced by significant assembly and operating factors such as static and dynamic balancing of rotor elements, alignment of connections, bearings condition, electromagnetic interference and others [3, 8, 9].

Proper operation of fans, particularly those of huge power and large diameters, not only decreases operating costs but also increases the safety of work. Their proper operation ensures constant air exchange and suction of dangerous gases in the mine pits, which along with safety systems [14, 15] protects pit mine workers. In the paper the results of vibrations tests of centrifugal fans responsible for ventilation of the mine are presented. Flow regulation of this type of fans is based on the fan airflow-pressure curve, where areas of unstable operation are located, which is unfavorable for the object. Tests performed during the machine operation allow to obtain key information for proper operation of the machine. Such tests are significant due to general lack of information regarding the subject of this type of machine behavior in the industry and because of the fact that the previous research was performed at a smaller scale in the laboratory.

3. Tested objects

The main ventilation system of a mine, which is the subject of the test, uses centrifugal fans denoted in Poland as WPK - 5,35, which in connection with the fan stations enable the mine ventilation. In the figure 1 the WPK-5.35 fan is presented.

Vibrations of casings, channels, inlet vanes and air shutters noticed during fans operation negatively influence the working conditions. In order to precisely specify the level and cause of vibrations the tests were performed during the start-up of each fan at the station. Additionally, the tests were performed during the opening of the inlet vanes (figure 2), in order to determine the influence of different flow effects occurring during that process on the level of fan vibrations.

4. Experimental tests

The goal of the tests was to record the vibrations velocity level in the ventilation systems during unsteady (start-up, opening of the inlet vanes) and steady states (regular operation). The tests were performed on the casings and intake channels of the fans and on the bearings housing of the rotors shafts. The identical arrangements of sensors, which is presented in the figures 3 and 4, were applied to all fans. Four WPK-5.35 ventilators, which cooperate within two different types of fan stations, were selected.
Sensors in the measuring channel 1 and 2 were placed on the housing of the shaft bearing located closer to the rotor. The sensors on the other seven channels were placed directly on the rotors casings and the intakes channels. A detailed description of directions and arrangement of sensors on particular channels is presented in the table 1. Setting directions of the sensors are in compliance with the coordinate system presented in the figures 3 and 4.

In the figure 5 the sensor on the channels no. 2 and 3 is presented. In the figure 6 the whole measuring system during the acquisition process is presented.

5. Tests results

Figures 7–10 present selected STFT diagrams recorded on the selected fan. Characteristic changes of frequency in particular phases of the fan operation are presented in the figure 7.

The change of the blade passing frequency, which increases during the start-up, is easily noticed. Less clear, but also noticeable, are vibrations coming from the start-up system. Their frequency decreases to 50 Hz when the fan operates with its nominal revolutions. Particular attention should be paid to the stage in which the fan achieves the nominal revolutions (375 rpm [19]) but the inlet vanes have not yet been opened. It is clearly recognized that this is an unfavorable moment for the system as it causes strong activation of vibrations in the whole range. After opening of the inlet vanes, the stable operation of the fan and related characteristic frequencies of vibrations are recognized. In all figures presenting spectrum vibrations recorded by sensors located on the casing (figure 7-9) the aforementioned blade frequency of the rotor amounting to about 50Hz is clearly noticed. Its harmonic 100 Hz and 150 Hz are observed as well. A detailed interpretation of vibrations visible on the STFT diagrams will be possible after performing numerical, experimental or operational modal analysis. As a result, mode shapes and frequencies of natural vibra-
The results obtained from the sensors recording bearing vibrations (in the figure 10 the spectrum of vibrations into the x direction is presented), tightly correlate with the fan casing vibrations, yet the level of acceleration is significantly lower. However, a significant difference in spectrums during the start-up and operation of the fan is noticed. During the start-up, the sensors located on the bearing do not record changes of blade velocity (vibrations are induced by the flow and influence only the fan casing). It is observable only after reaching the nominal velocity, when the flow pulsations are strong enough to influence the whole system. Also, a frequency not recorded on the fan casing amounting to about 6.25 Hz occurs. This corresponds with the rotary frequency and vibrations are induced by an unbalance of the shaft and rotor.

In the case of other fans, vibrations spectrums are similar. What distinguishes particular fans is a difference between duration of the start-up and opening of the inlet vanes. In the first case the start-up of the fan proceeded efficiently and it is difficult to notice on the STFT spectrum changing blade and start-up frequencies, as they after a while decline in the vibrations of the whole system caused by still unopened inlet vanes. The list of the vibrations levels is presented in the table 2.

In the table the levels of maximum vibrations and root mean square (RMS) of vibrations for an unsteady state (start-up and opening of the inlet vanes) and for a steady state (operation with a nominal rotary velocity and open inlet vanes) are presented. In order to verify in which case (on which fan) the situation is the least favorable, the vibrations levels in particular channels are compared. The color font of the values indicates the maximum value of vibrations velocity or RMS in a particular channel (in the particular measuring point) recorded in an unsteady state among all tested fans. The values in the color boxes indicate respectively the maximum value of vibrations velocity or RMS in the particular channel (in the particular measuring point) recorded in a steady state among all tested fans.

### 6. Summary and conclusions

Tests presented in the paper were performed in the real operation conditions. These allowed to specify characteristic frequencies and levels of forced vibrations of large sizes, power and efficiency centrifugal fan elements.

The vibrations analysis performed with the use of the Short Time Fourier Transform presented changes in the level and frequency of vibrations which correspond with particular phases of fans start-up sequences. As a result strong transient states in the process of operation of tested objects were identified. By verification of the received vibration spectrum characteristics, primary excitation frequencies were distinguished: rotary frequency of the rotor, blade passing frequency and their harmonic frequencies. Excitation in the wide frequency band noticed during opening of the inlet vanes results from the operation of the fan the region of instability (located on the left side from peak pressure point on fan airflow-pressure curve).

Apart from identifying of operation conditions of the fans for its different states it was also possible to compare characteristic parameters and make conclusions on the technical conditions of the objects tested and potential correction operations.

On the basis of tests performed, a huge discrepancy of vibrations level on particular fans was noticed. The highest level both in the steady and unsteady state is related to the W1 fan. It has the most
maximum values of the RMS. This indicates a general high level of vibrations.

Similar situation occurs in the case of the W4 fan at the station. However, a significant difference is the fact that the largest number of extreme values is recognized for the maximum acceleration levels. This indicates that instantaneous accelerations of a high value occur.

Vibrations levels of the other two fans are significantly lower compared to the abovementioned.

The observed results confirm occurrence of diverse and inappropriate (too long) duration of fans start-ups. The occurrence of vibrations is also caused by the following factors: unnecessary keeping fans in motion while the radial vane inlet control is unopened, inappropriate unbalance of the rotary systems or inappropriate regulation of inlet vanes.

Also, a discrepancy between the vibration levels of particular fan casings is noticed. It may be however specified that in the channel of inlet vanes.

casings either during the operation or with numerical or experimental methods [24]. After confirmation of this thesis it will be possible to implement construction changes in order to relocate the natural frequency of casings into the higher range.

Tests presented in the paper allow to identify operation conditions of complex mechanical-flow systems such as turbomachines. Operation of this type of machines is connected with numerous problems, which mainly result in different type of vibrations of particular elements or the whole group. The proper interpretation of reasons for their occurrence allows to make quick modifications in order to increase durability, decrease possibility of failure or allow further safe operations. In the case of huge power turbomachines, which were subject of the tests, the scale of these objects draws particular attention to the observed irregularities, whose symptoms are the increased levels of vibrations. In the case of this type of objects it is worth to consider installation of systems of periodical or constant monitoring of vibrations, recognized not only in the bearing support of the power transmission system, as it is right now, but also in the areas whose vibrations allow the early identification of potential problems. These areas are e.g. inlet vanes, fan casings etc. Additionally, it is accurate to monitor the flow parameters such as fan pressure ratio, flow machine efficiency and correlate them with the vibration signals. Such an attitude allows to fully identify phenomena occurring in different states of the machine operation and interpret them correctly. The next step should be to verify the influence of tested phenomena on the condition of the object. Numerical methods (FEM, BEM, FDM), which allow to perform simulations reflecting real (measured) operating conditions and predict its influence on the technical condition of the object, may be here applied.
