This work is the continuation and refinement of already published communications based on PET/EG nanocomposites prepared by in situ polymerization¹,². In this study, nanocomposites based on poly(ethylene terephthalate) with expanded graphite were compared to those with functionalized graphite sheets (GO). The results suggest that the degree of dispersion of nanoparticles in the PET matrix has important effect on the structure and physical properties of the nanocomposites. The existence of graphene sheets nanoparticles enhances the crystallization rate of PET. It has been confirmed that in situ polymerization is the effective method for preparation nanocomposites which can avoid the agglomeration of nanoparticles in polymer matrices and improve the interfacial interaction between nanofiller and polymer matrix. The obtained results have shown also that due to the presence of functional groups on GO surface the interactions with PET matrix can be stronger than in the case of exfoliated graphene (EG) and matrix.

Keywords: in situ polymerization, PET, graphene oxide, expanded graphite.

INTRODUCTION

One of the most widely used semi-crystalline polyesters in the world is poly(ethylene terephthalate) (PET) as a thermoplastic polymer material. For some time now, PET has expanded its applications in a variety of fields, ranging from fibers to films and magnetic recording tape substrates³,⁴. Although PET has balanced properties of mechanical strength, thermal property, and barrier property for commodity and engineering applications, the further improvement in thermal and mechanical properties of PET is needed to pursue for high performance applications.

Incorporation of nanofillers in a polymer matrix gives rise to a new class of materials known as polymer nanocomposites, which have better potential for many applications. Polymeric nanocomposites have been a topic of great interest for the last two decades for scientists all over the world. Numerous researchers have already reported the effect of different nanofillers like clay, carbon nanotubes, graphene and graphene derivatives and silica on polymer properties⁵-⁸. Development of nanocomposites from various clay, carbon nanotubes and graphene derivatives has been discussed in several publications from our laboratory group⁵-⁷,⁹-¹². Among those nanofillers, graphene sheet, a 2-dimensional monolayer of sp²-bonded carbon atoms arranged in a honeycomb network, has been recently considered as an ideal reinforcing material to enhance the thermal, mechanical, and electrical performances of polymeric materials due to its outstanding thermal stability, mechanical modulus, and in-plane electrical conductivity¹²-¹⁸. Accordingly, PET-based nanocomposites containing graphene sheets have been also prepared and their structures and electrical properties have been investigated¹⁶-¹⁷. However, the influence and comparison of EG and GO on poly(ethylene terephthalate) based nanocomposites prepared by in situ polymerization have not been investigated systematically.

In this work, the influence of expanded graphite (EG) and graphene oxide content on the synthesis process and physical properties of poly(ethylene terephthalate) (PET) is investigated. For this purpose, PET/EG and PET/GO nanocomposites at different nanofiller loadings were prepared by in situ polymerization.

EXPERIMENTAL

Material

For the poly(ethylene terephthalate) (PET) synthesis the following chemicals were used: dimethyl tereftalate (DMT) (Sigma-Aldrich); ethane-1,2-diol (Sigma-Aldrich), zinc acetate Zn(CH₃COO)₂ (Sigma – Aldrich) as an ester exchange catalyst; antimony trioxide Sb₂O₃ (Sigma – Aldrich) as a polycondensation catalyst; Irganox 1010 (Ciba-Geigy, Switzerland) as a thermal stabilizer. EG was prepared by thermal expansion (SGL Carbon SE, Germany); average thickness of the expanded agglomerates was 450–560 nm. Graphene platelets size ranged from 16 μm to 46 μm (99%). Graphite oxide (GO) with flake size of about 5 μm was provided by Polymer Institute of Slovak Academy of Sciences, where the natural graphite was first converted to intercalated or expandable graphite through chemical oxidation in the presence of concentrated H₂SO₄ and HNO₃ acids. Before adding nanofillers to the reaction mixture they were combined with ethanediol in order to split agglomerates and to improve further exfoliation. Polymer nanocomposites PET/EG and PET/GO have been synthesized following the same procedure⁴.
Preparation of PET/EG and PET/GO nanocomposites

Nanocomposites based on poly(ethylene terephthalate) (PET) were prepared by in situ polymerization in the polycondensation reactor (Autoclave Engineers, Pennsylvania, USA) capacity of 1000 cm³. The process was conducted in two stages, followed the same procedure as published elsewhere¹,²,⁹–¹¹,¹⁸. In the first stage, at atmospheric pressure and temperature range of 175 ± 190°C, took place transesterification reaction between both dimethyl terephthalate (DMT) and ethylene glycol with the addition of nanofiller (EG, GO), which was initially dispersed using high-speed stirrer (Ultra-Turax T25), sonicator (Homogenizer HD 2200, Sonoplus) and ultra-power lower sonic bath (BANDELIN, Sonorex digittec), resulting in the precipitation of methanol. When a precipitated amount of alcohol was close to the theoretical amount, the pressure was gradually lowered to about 0.1 hPa and the second stage was begun. Polycondensation carried in temperature to 275°C by the stirrer speed 40 rot/min. The progress of this step of reaction was monitored based on observations of the changing viscosity of the reaction mixture, which was in turn monitored on the basis of observations in torque stirrer during the synthesis. The reaction was considered complete when the viscosity in the system rose to 14 Pa · s. The obtained polymer/nanocomposite was extruded from the reactor at a pressure.

Characterization methods

The inherent viscosity [η] of the polymers was determined at 30°C using a capillary Ubbelohde type of PET homopolymer was used to calculate the viscosity average molar mass of reaction. The density was measured at 21°C on hydrostatic balance (Radwag WPE 600C, Poland), calibrated for standards with known density.

To evaluate the actual amount of nanofiller, the polymer nanocomposites with the nanofiller content of 0.4 wt.% solution was filtered through 0.2 μm pore size polytetrafluorethylene (PTFE) filter (Whatman; membrane type TE 35). For this purpose, expanded graphite and graphene oxide from the known mass of the nanocomposite have been filtered through 0.2 μm pore size polytetrafluorethylene (PTFE) filter (Whatman; membrane type TE 35). After filtration the polymer was precipitated and re-dissolved. The Mark-Houwink relationship [η] = 3.72 · 10⁻⁴ · M₀.⁷³ was used to calculate the viscosity average molar mass of PET homopolymer

The melt volume rate (MVR) was measured by using a melt indexer (CEAST, Italy) as melt flow in cm³ per 10 min, at temperature of 280°C, and at orifice diameter 1.050 mm and under 2.160 kg load, according to ISO 1133 specification.

The density was measured at 21°C on hydrostatic balance (Radwag WPE 600C, Poland), calibrated for standards with known density.

To evaluate the actual amount of nanofiller, the polymer nanocomposites with the nanofiller content of 0.4 wt.% solution was filtered through 0.2 μm pore size polytetrafluorethylene (PTFE) filter (Whatman; membrane type TE 35). For this purpose, expanded graphite and graphene oxide from the known mass of the nanocomposite have been filtrated. After filtration the polymer was precipitated, re-dissolved and weighted. The PTFE filter, with nanofiller on the surface, after filtration and vacuum drying was also weighted.

The thermal properties of PET based nanocomposites were studied with differential scanning calorimetry (DSC, TA Instruments Q-100, USA, 2004) in cycle: heating – cooling – heating in the temperature range from -50 to 300°C at a scan rate of 10°C/min. The second heating and cooling scans were used to determine the melting and crystallization peaks. The glass transition temperature (T_g) for the prepared nanocomposites and pure PET was taken as the midpoint of the change in heat capacity. The degree of crystallinity (X_c, mass fraction) was calculated using the formula:

\[ X_c = \frac{\Delta H_m}{\Delta H_m^0} \times 100\% \]  

where: \( \Delta H_m \) – enthalpy of melting of the measured sample, J/g; \( \Delta H_m^0 = 140.01 \) J/g – the theoretical value of enthalpy for 100% crystalline PET

RESULTS AND DISCUSSION

Morphology and phase structure

To investigate the dispersion quality of expanded graphite (EG) and graphene oxide (GO) particles, the morphology of PET/EG and PET/GO composites were studied by TEM and SEM and the results are shown in Figure 1. The obtained nanocomposites exhibit a relatively homogenous distribution with highly exfoliated EG and GO in PET matrix. On TEM images the more and less transparent few layer graphene/graphene oxide (Fig. 1a–b) were observed. It can also be seen from Figure 1 that the sizes of both the modified and unmodified graphene sheets are mostly in the range of 5–20 μm except the aggregated sheets, suggesting that in situ polymerization is a effective method for preparing nanocomposites. However, no big difference in the level of filler dispersion/exfoliation was observed on SEM images between GO and EG-filled composites at 0.4 wt%, suggesting that at low loadings the presence of functional groups on the surface of GO does not lead to significant improve exfoliation of GO in PET matrix. However, the observations of more embedded GO platelets (Fig. 1d) in polymer matrix GO can suggest the interactions between functional groups of GO and PET matrix. The presence of functional groups such as carboxylic groups on GO surface can improve interfacial adhesion between graphene and polymer matrix mainly due to the possible interaction of hydrogen bonding between the COOH groups of GO and the ester groups in polymer matrix. Such behaviour was observed for carboxy-functionalized carbon nanotubes PET, PEN nanocomposites ²¹–²². Moreover, the observed also folded/wrinkled surface texture of the few layer graphene/graphene oxide (Fig. 1a–b) can play an important role in enhancing mechanical interlocking and load transfer with the matrix.

Physical properties of nanocomposites

Values of [η] for polymer nanocomposites after nanofiller filtration are varied between 0.49 and 0.55 dl/g and
they are close to the value obtained for the neat PET (0.536 dL/g). As can be seen in Table 1, the obtained values of $[\eta]$ show that the synthesized nanocomposites have high molecular weights with a slight decrease with the increasing content of both nanofillers (EG and GO) from $2.12 \times 10^4$ for PET to $1.87 \times 10^4$ for PET/0.4GO nanocomposite after nanofiller filtration.

A slight reduce in the MVR only for nanocomposite with 0.1 wt.% of graphene oxide and no changes for PET/0.4GO was observed. Both nanocomposites, with 0.1GO and 0.4GO have similar molecular weights but lower than pure PET. The comparable value of MVR for PET and PET/GO nanocomposites was due to the polymer – functionalized graphene sheets interactions. The presence of EG and GO affects the viscosity of the melt in the synthesis of nanocomposites which reduced the molecular weight of the PET matrix in obtained nanocomposites. Moreover, with the same content (0.1 and 0.4 wt.%) of EG and GO nanofillers the differences in their impact on the molecular weight of PET matrix in nanocomposites and the viscosity of the melts was observed. For PET/EG nanocomposites the slight reduction in molecular weight at 0.4 wt% of EG content in the composite resulting in reduced melt viscosity (higher values of MVR). The large increase from 72.8 (for pure PET) to 118.9 cm$^3$/10 min for PET/0.4EG can be also due to lack of polymer-expanded graphite interactions.

Nanocomposites in comparison to the neat polymer have slightly higher density due to the presence of nanofiller with higher density (Table 1).

The obtained nanocomposites with the highest content of nanofillers (0.4 wt.% of EG and 0.4 wt.% of GO) were tested for the actual content of nanofiller in the, prepared via in situ polymerization, nanocomposites. The subsequent steps of performed experiment are shown in Figure 2. The nanocomposite was dissolved in mixture phenol/1,1,2,2-tetrachloroethane (60/40 by weight) in the Erlenmeyer flask (Fig. 2a). After filtration in vacuum,

PET modified CNT nanocomposites have shown that the variations of the nucleation activity and the crystallization activation energy of the PET nanocomposites reflected the enhancement of crystallization of the PET nanocomposites effectively induced by a very small quantity of the carboxylic acid groups-induced CNTs (c-CNTs). The incorporation of the c-CNTs into the PET matrix remained nanofiller no longer (Fig. 2b), what confirms the transparent color of the solution. After complete separation of the nanofiller from the nanocomposite the teflon filter has been dried and weighed (Fig. 2c). The conducted experiment confirmed that using in situ polymerization as a method of preparing polymer nanocomposites allows to retain an uniform and quantitative composition in the entire volume of obtained sample in relation to the output composition.

**Thermal properties**

The effect of expanded graphite and graphene oxide on the thermal behaviour of the nanocomposites and neat PET during heating and cooling was examined by DSC (Table 2, Fig. 3). As can be seen from the Table 2, the glass transition temperature was not affected by the presence of EG and GO in polymer matrix. Degrees of crystallinity of the nanocomposites are comparable to those neat PET. The rate of crystallization was shown to depend strongly upon molecular weight\(^{23}\). However, the crystallization traces in Figure 2a indicate that GO worked as a nucleation agent for the crystallization of PET. The lower molecular weights also have the influence on crystallization of PET matrix in prepared nanocomposites, what have been also shown in recent study\(^{24}\). At the same cooling rate, the nanocomposites with 0.4 wt.% of EG and 0.4 wt.% of GO show higher crystallization temperatures (Fig. 3a, Table 2). The degree of supercooling (\(\Delta T = T_m - T_c\)) may indicate a polymer’s crystallizability; that is, the smaller the \(\Delta T\), the higher the overall crystallization rate. The \(\Delta T\) values for the nanocomposites are smaller, by 36–38°C, than that of neat PET (43°C). Nanofiller usually affect the ability to crystallize semi-crystalline polymers\(^{25-27}\). Distributed in the polymer matrix nanoparticles can assist by nucleation and growth of crystallites. Crystallization rate of a polymer is determined by the nucleation rate and mobility of polymer chains. Recent study on crystallization process in

![Figure 3. DSC thermograms for PET/EG and PET/GO nanocomposites with different nanofillers concentration during: a) cooling and b) 2nd heating](image)
has a significant effect on the non-isothermal crystallization kinetics of the PET nanocomposites in that the c-CNTs dispersed in the PET matrix can effectively act as strong nucleating agents and lead to the enhanced crystallization of the PET nanocomposites through heterogeneous nucleation. Similar observations have been reported that the crystallization of CNT/polymer nanocomposites was accelerated by the presence of CNT through heterogeneous nucleation. It has been also already published, that in PET/EG nanocomposites the addition of EG changed the crystallization mechanism, accelerated the crystallization rate, but decreased the crystallinity of the PET resin. The introduction of nanofiller produces a hindrance on the molecular chains movement, which will reduce the tendency for molecular chains to be crystallized, though the confined molecular chains may be well ordered in the lamellar space. Although, in our case only increase of crystallization rate was observed, but degree of crystallinity is not affected by the presence of the EG and GO.

CONCLUSIONS

The aim of this study was to investigate the influence of functionalized (GO) and non-functionalized (EG) carbon nanofillers on the synthesis process of PET based nanocomposites. In particular, the addition of nanofiller to the semicrystalline polymer matrix may influence on its crystallization. In our systems, increase of crystallization rate was observed, but degree of crystallinity is not affected by the presence of both: expanded graphite and graphene oxide. The crystallization traces indicate that GO worked as a more effective nucleation agent for the crystallization of PET. The high dispersion level of oxidized graphene sheets can be attributed to a strong interaction between functionalized groups on the surface of GO and the polar groups of PET (Fig. 1). It was characterized that disordered graphene sheets of EG and GO are well dispersed in the PET matrix without interactions. Nanocomposites in comparison to the neat polymer have slightly higher density due to the presence of nanofiller with higher density.
