Application of Power Ultrasound to Chemical Dissolution for Quantitative Analysis of Cotton and Polyester Blended Fabrics

Abstract

In this paper, the feasibility of applying ultrasonic technology to quantitative analysis of cotton and polyester blended fabrics by the chemical dissolution method is explored. Four varieties of blends with different cotton contents were employed and dissolved in sulfuric acid solution with ultrasound assistance. Although three different frequencies: 20, 28 and 40 kHz were adopted, the experimental results indicate that there is no difference between them. For some fabrics that cannot be untwisted into yarns, ultrasonic technology has good experimental results while only needing a fabric form prepared from a small, long strip. By comparison with the traditional mechanical oscillation method stated in ISO 1833-11:2006, the more meaningful role of ultrasonic lies in the fact that the experimental time and usage of solvent can be reduced by half, which is in agreement with resource savings and environmental protection. Broadly speaking, the study demonstrated that ultrasound assisted chemical dissolution for the quantitative analysis of cotton and polyester blended fabric is feasible.

Key words: power ultrasound, chemical dissolution, quantitative analysis, cotton, polyester, blended fabrics.

Introduction

The fibre content of blended fabric has an important influence on fabric performance, style and production price, which also is a vital identification for the textile trade. Physical separation, chemical dissolution and the microscopic method have been the most commonly used quantitative analysis methods in the past decade. Especially chemical dissolution, which has been used for a few decades, is accurate and robust in textile quantitative analysis [1]. After dissolving one component in an appropriate chemical reagent, the content was calculated by precise weighing. One by one, all the fibre contents were obtained with different chemical solvents. However, a large amount of laboratory technicians were needed, and they had to come in direct contact with the chemical reagent, which would cause health issues [2]. Because of a lack of optimal control, the excessive use of auxiliary chemicals has created environmental issues [3]. What is more, the applying of mechanical agitation in the process of chemical dissolution was inconvenient for the mechanization and automation of textile quantitative analysis. As there was an urgency to improve testing efficiency, a more rapid and efficient method was required.

The power ultrasound technique, with the advantages of penetrating the isolation layer on the fibre and promoting solvent diffusion, has long been studied as an alternative to the conventional method during some textile process such as dyeing [4], bleaching [5] and washing [6]. Its remarkable benefits come from heating and cavitations. The formation of rapid collapse of micro-bubbles formed by ultrasonic waves are generally considered responsible for most of ultrasound’s physical and chemical effects. Dyeing with intermittent ultrasound was confirmed to be more effective than making full use of ultrasound energy continuously [7]. Compared with the conventional process, raw wool washing with ultrasound can lower the process temperature and provide the same results [8]. In addition, scouring wool in small batches using ultrasonic techniques reduced water and detergent consumption and shortened the time of scouring without damage and entanglements [9]. There were also researches that indicated that the powerful agitation of the liquid border layer caused by cavitation could increase the reaction rate of enzymatic desizing [10, 11]. From the investigations above, it can be seen that ultrasound has been employed to fabric wet processing with good effects. However, few applications of ultrasound for quantitative analysis of blended fabrics have been found.

In this paper, quantitative analysis of blended fabrics by the chemical dissolution method assisted by ultrasound is carried out, and by comparison with the traditional mechanical oscillation method, the advantages of the ultrasonic technique are verified. Considering the universality, blended fabrics composed of cotton and polyester were used as the experimental material, where cotton was selected as the component to be dissolved. As in the process of the traditional chemical dissolution method, according to ISO 1833-11:2006, blended fabrics were dried and weighed in the beginning. After dissolution, the fibres removed from the initial specimen were determined by the loss of weight measured by a precision electronic balance. The advantages of applying ultrasound in chemical dissolution for quantitative analysis of blended fabrics are embodied by the prospect of lowering the dissolving time, reaction temperature, and amount of solvent usage etc.

Materials and methods

Materials

Four types of cotton and polyester blended fabrics with different cotton contents were employed in this study. The cotton content of each fabric, measured by the traditional method, is considered as the standard value. These four blended fabrics shown in Table 1 are commercial samples and are provided by the Shanghai Textile Research Institute.

According to ISO 1833-11:2006, 75% of the mass fraction of the sulfuric acid solution is chosen as the solvent for cot-
Experimental procedure

BL6-180A (BiLon Ltd., Shanghai, China) ultrasonic cleaners with a frequency of 20, 28 and 40 kHz, respectively, are used as a source of mechanical action for auxiliary dissolving. The ultrasonic cleaners with a thermo-controlled bath of capacity 6l can reach a temperature up to 80 °C.

Blended fibres are submerged in a glass beaker containing an exact amount of solvent, where the dissolving process is carried out. The glass beaker is immersed in a water bath of the ultrasonic cleaner at a certain temperature. After dissolving, the remaining fibres are rinsed with neutralisation solution and distilled water, then vacuum filtered to a sand core crucible. Next the sand core crucible with insoluble fibres is dried in a thermostatic drying oven (HOC-9030A, Hengqian Technology Ltd, Shanghai) for more than 4 hours (no more than 16 hours), maintaining a temperature of (105±3) °C. After drying, it is cooled in a drying vessel at ambient temperature for half an hour, and finally weighted by a BSA124S-CW Sartorius, with an accuracy of 0.1 mg.

For clarity, the whole process of experiment is shown in Figure 1, from which it can be seen that the difference between the ultrasonic method and traditional mechanical oscillation method is only in the dissolving procedure.

Experimental results evaluation

The content of the dissolved component is evaluated by the weight loss after dissolving, which is expressed by the following Equation (1):

$$WL = \frac{W_r - W_s}{W_s} \times 100\% \quad (1)$$

Where, WL represents the content of dissolved fibre, $W_r$ and $W_s$ are the weights of the blended fabric before and after dissolution, respectively.

From Figure 2, it can be seen that data obtained by the three ultrasound frequencies are acceptable as the biggest difference is no more than 1%. With the sign test, the three data sets are analysed two by two at a 5% significance level. Results showed that there is no difference between the three ultrasound frequencies when applied to quantitative analysis by chemical dissolution.

Effect of dissolving time

30 minutes was applied at the frequency given above, which is much less than the standard value of 60 minutes according to ISO 1833-11:2006. For further research of the influence of time, blended fabric FS2 was dissolved at 50 °C at a liquor ratio of 100 (ml/g) and ultrasound of 20 kHz. The blended fabric was cut into 20 pieces, each weighing about 1 g, and then untwisted into yarns. The 20 fabric pieces were divided into four groups equally for dissolving for 20, 25, 30 and 35 minutes, respectively.

From Figure 3, it can be seen that cotton is dissolved almost completely even after 20 minutes. However, the error bar shows that data fluctuation is a little wider than for the other three dissolving times, which means that dissolving for 20 minutes is unstable. For 25 minutes

dissolving, the mean value is closer to the standard value and the error bar is smaller. When dissolving for 30 minutes, both the mean value and error bar suggest that cotton is dissolved completely and steadily, which can be verified by the results for 35 minutes dissolving. Hence cotton dissolving for 30 minutes is considered optimum for quantitative analysis of blended fabrics by ultrasound.

Influence of experimental temperature

According to ISO 1833-11:2006, the standard temperature was 50 °C for cotton dissolution. On the one hand, higher chemical reaction temperature goes against improvement of ultrasonic efficiency. On the other hand, energy conservation needs a lower dissolution temperature. Hence blended fabric FS3 is used for investigating the influence of temperature on quantitative analysis with an ultrasound of 20 kHz. The blended fabric is cut into 15 pieces, each weighing about 1 g, and then untwisted into yarns. The 15 fabric pieces are divided into three groups equally for dissolving at 30, 40 and 50 °C, respectively. Of course, the dissolving time is 30 minutes and the liquor ratio is 100 (ml/g) in the experiment.

From the left graph in Figure 4, it is observed that the cotton contents obtained at 30 °C and 40 °C are closer and much less than the results dissolved at 50 °C. However, when dissolved at 50 °C, the results are almost around the standard value of 76.4% and the biggest difference is no more than 1%. From the mean value and standard deviation on the right graph, it is also suggested that cotton is dissolved sufficiently and is stable at 50 °C. Hence for cotton dissolved by sulfuric acid solution, the experimental temperature cannot be lower when assisted by ultrasound.

Influencing of fabric forms

In the previous discussion, all the blended fabrics are untwisted into yarns for experiment, and good effects are obtained. However, there are blended fabrics that cannot be untwisted into yarns, and finding an alternative fabric form is necessary. Blended fabric FS1 is used and divided into two parts: Part one is cut into pieces weighing about 1 g and shredded into strips of about 0.1 cm × 0.5 cm, meanwhile part two is cut into pieces weighing about 1 g and untwisted into yarns of about 1.5 cm long. From each part ten specimens are prepared, which are dissolved by ultrasound of 20 kHz.
It can be seen that all the data are valid when considering 1% tolerance. It can be reasonably stated that if the cotton is dissolved sufficiently with the two fabric forms, the two data sets will follow the same Gaussian distribution. At a 5% significance level, the two groups are analysed. Results indicate that there is no difference between the two data sets, which means the fabric form shredded into strips is an effective alternative for blended fabric that cannot be untwisted into yarns.

**Influence of liquor ratio**

The liquor ratio, defined as the ratio of dye solution and fabric in the textile dyeing industry, is defined as the ratio of solvent (ml) and fabric (g) in this study. For quantitative analysis of blended fabrics by the method of chemical dissolution, the standard liquor ratio was 100, which deserved further research for the purpose of resource savings and environmental protection. Blended fabric FS4 is employed for discussing the influence of liquor ratio on quantitative analysis with ultrasound. The blended fabric is untwisted into 24 yarn pieces, each weighing about 1 g, and the 24 fibre pieces are divided into 8 groups equally corresponding to a liquor ratio of 10, 15, 20, 25, 30, 50, 70, and 100. The dissolving time is 30 minutes and the experimental temperature 50 °C.

The results of cotton fibres dissolved in blended fabric by ultrasound with different liquor ratios are shown in Figure 6, from which it can be observed that cotton is dissolved quickly, even when the liquor ratio is 10. When up to 15, both the mean value and error bar indicate that cotton is dissolved sufficiently and steadily. This finding suggests that the solvent was excessive for quantitative analysis of blended fabric by the traditional method. However, a small liquor ratio may cause a big random error because it is obvious that fibres are not easily or sufficiently immersed in the solvent. By observing the process of the dissolving experiment, a liquor ratio of 50 is considered optimum for quantitative analysis of blended fabrics by ultrasound.

### Conclusions

The traditional method for quantitative analysis of blended fabrics by chemical dissolution was used for manual operation; especially mechanical oscillation and glass rod stirring were adopted in the dissolving process. Owing to the requirement for work efficiency and testing precision, the feasibility of ultrasonic technology applied in quantitative analysis of cotton and polyester blended fabrics by chemical dissolution method is investigated.

1. According to the analysis of ultrasound frequency, it can be seen that there is no difference between the three frequencies of 20, 28 and 40 kHz.
2. Although the standard dissolving time was 60 minutes according to ISO 1833-11:2006, the experimental time of cotton dissolution can be reduced to 30 minutes when applying ultrasonic technology.
3. However, the experimental temperature has to be consistent with the standard value of 50 °C, which may be determined by the properties of the solvent and dissolved fabric.
4. Test specimens should be prepared in small long strips if the blended fabric cannot be split into yarns, for there is no difference between them during dissolution assisted by ultrasound.
5. A more meaningful role is played by ultrasonic technology applied in chemical dissolution as the solvent can be reduced by half, which is conducive to resource savings and environmental protection.

In general, the study demonstrated that ultrasound assisted dissolution for quantitative analysis of blended fabrics is an efficient method, which is better than the traditional mechanical vibration method in some ways.
