Department of Electrical Engineering, Pontifical Catholic University of Rio de Janeiro Rua Marqus de So Vicente, 225, Gvea – Rio de Janeiro, RJ, Brazil

Abstract

This work presents a Genetic Fuzzy Controller (GFC), called Genetic Programming Fuzzy Inference System for Control tasks (GPFIS-Control). It is based on Multi-Gene Genetic Programming, a variant of canonical Genetic Programming. The main characteristics and concepts of this approach are described, as well as its distinctions from other GFCs. Two benchmarks application of GPFIS-Control are considered: the Cart-Centering Problem and the Inverted Pendulum. In both cases results demonstrate the superiority and potentialities of GPFIS-Control in relation to other GFCs found in the literature.

1 Introduction

Fuzzy Logic Controllers (FLCs) [1,2] have been extensively used as an alternative to manipulate and describe complex systems when traditional control methods do not provide viable solutions. FLCs have the capacity of modeling systems by using fuzzy "if-then" rules, normally provided by an expert. Classical fuzzy logic approaches employ either a Mamdani-type Fuzzy Inference System (FIS) [2-3] or a Takagi-Sugeno (TSK) FIS [4-5] and both have different parameters that must be tuned in order to obtain the best performance, such as rule base, membership function parameters, etc. These parameters can be tuned manually by an expert or automatically by employing a learning approach. In this respect, this work considers Genetic Fuzzy Systems [3,6], or, more specifically, Genetic Fuzzy Controllers.

In Genetic Fuzzy Controllers (GFC) the automatic learning and tuning of parameters is based on a Genetic-based Meta-Heuristic (GBMH). Some previous works have considered FLCs embedded with a Genetic Algorithm (GA) to tune membership function parameters [7-8] or to search for concise fuzzy rule bases [9-10]. More recently, some works have explored Genetic Programming (GP) to build an FLC by using methodologies and concepts similar to those employed on a GA based FLC [11-12].

In general, it is advantageous to use a GBMH exclusively to search for the FLC best configuration. In this perspective, the meta-heuristic is seen as a tool to build an FLC and not as a mechanism that may change reasoning. Still, in frameworks with a high level of hybridization, in which a genetic-based meta-heuristic has a higher participation, it may be possible to obtain better accuracy. Examples are Neuro-Fuzzy models [13,14], where Neural Networks play an important role in the hybrid architecture, enabling high accuracy and fast convergence.

This work proposes a new GFC called Genetic Programming Fuzzy Inference System for Control tasks (GPFIS-Control). It makes use of Multi-Gene Genetic Programming [15-16] for extracting knowledge from the plant. The resulting architecture should: (1) automatically tune the FLC parameters; (2) make the plant output reach the setpoint as fast as possible; (3) provide linguistic comprehension for each FLC action; and (4) be easy to implement.

This paper is organized as follows: Section 2 describes related works on GFC and considers some applications involving GP. Section 3 describes Multi-Gene Genetic Programming and its basic differences from standard Genetic Programming strategy. Section 4 presents the proposed GPFIS-Control in detail. Case studies are considered in Section 5 and section 5 concludes the work.

2 Related Works

The first attempt to build an FLC by using GBMH algorithms was presented in [7], where a GA was used to tune membership functions parameters of input and output variables. Subsequently, many other researchers have employed evolutionary algorithms, mostly GA, to tune FLC parameters and search for concise rule bases [17-19].

Several works can be found in the GFC area, such as [9], which presents an evolutionary procedure to modify rules, initially set by an expert, for a Mamdani type FLC. In [20], membership functions, rule sets and consequent types (TSK or Mamdani types) are tuned by a GA. Two other approaches are: [8], which employs linguistic hedge operators, selected by a GA, to tune membership functions, and [10] where a hierarchical self-organized GAbased scheme is proposed.

Recently, most works that make use of GA to tune FLCs focus on real applications [19, 21, 22]. Type-2 FLCs have also been tuned through GA [18]. Additionally, some non-GBMH works for tuning an FLC have also considered Particle Swarm Optimization [23] and other bio-inspired algorithms [24].

Few attempts, however, have been made to build an FLC by using GP, despite its dynamic structure that benefits rule base codification [6]. The first works in this sense were [25] and [26], which used a type-constrained GP to build a fuzzy rule based system. In [27] an FLC based on GP for mobile robot path tracking is presented. More recently, [12] proposes the use of a GP variant to build a TSK FLC. All those approaches adapt the GP structure to formulate an FLC in a canonical way, similarly to a GA common procedure. Some intrinsic advantages of GP are effectively used by these authors, but many possibilities arise, such as the use of combinations of different t-norms and tconorms, of linguistic hedges and of different aggregation operators.

All approaches previously discussed focus on Pittsburgh-type GFC, i.e., an individual of the population encodes a whole fuzzy rule set [3,6]. Then, methods that consider an individual as a fuzzy rule – Michigan, Genetic Cooperative-Competitive Learning and Iterative Rule Learning – have not been noticed in the literature [17].

GPFIS-Control is a novel GFC based on Multi-Gene Genetic Programming. This model builds a Pittsburgh-type Fuzzy Rule Based System, making use of a different reasoning method to learn fuzzy rules.

3 Multi-Gene Genetic Programming

Genetic Programming (GP) [28-29] belongs to the Evolutionary Computation field. Typically, it employs a population of individuals, each of them denoted by a tree structure that codifies a mathematical equation, which describes the relationship between the output Y and a set of input terminals X_i (*j*=1,...,J) (features, in the current work).

Multi-Gene Genetic Programming (MGGP) [15-16] denotes an individual as a structure of trees, also called genes, that receives X_j and tries to predict Y (Figure 1). Each individual is composed of D functions f_d (d=1,...D) that map X_j variables to Y through user-defined mathematical operations. In GP terminology, the X_j input variables are included in the Terminal set, while the mathematical operations (plus, minus, etc.) are inserted in the Function Set (or Mathematical Operations Set).

Figure 1. Example of a multi-gene individual

With respect to genetic operators, mutation in MGGP is similar to that in GP. As for crossover, the level at which the operation is performed must be

specified: it is possible to apply crossover at high and low levels. The low level is the space where it is possible to manipulate the structures (terminals and functions) of equations present in an individual. The high level, on the other hand, is the space where expressions can be manipulated in a macro way. In this case, mutation and low level crossover operations are similar to those performed in GP. Figure 2 presents a multi-gene individual with five equations (D=5). Figure 2a shows the mutation operation, while Figure 2b a low level crossover.

An example of high level crossover is displayed in Figure 2c. By observing the dashed lines, it can be seen that the equations were switched from an individual to the other. The cutting point can be symmetric – the same number of equations is exchanged between individuals –, or asymmetric. Intuitively, high level crossover has a deeper effect on the output than low level crossover or mutation has. In of the proposed GPFIS-Control model, the asymmetric high level crossover is considered.

In general, the evolutionary process in MGGP differs from GP due to the addition of two parameters: maximum number of trees per individual and high level crossover rate. For the first parameter, a high value is always used in order to avoid creating obstacles in the evolutionary process (i.e., not allowing the MGGP individual to create more trees, which could be necessary to provide solutions for complex problems). On the other hand, the high level crossover rate, similar to other genetic operators' rates, needs to be adjusted and its value is always determined by performing different tests.

4 GPFIS-Control

The GPFIS-Control model is shown in Figure 3. The control signal y_t is sent to the plant at time t (t=0, 1, ..., T). The plant outputs z_{tk} (k=1,...K) are compared with the setpoint value, so that the result of the difference between each plant's output and its respective setpoint (the error signal $x_{tk} = z_{tk} - \text{Ref}_k$) is presented to the GPFIS-Control model. By using x_{tk} it is possible to build a control signal y_t to satisfy a performance criteria (Fitness function $g(x_{tk}, t)$).

The GPFIS-Control model is comprised of four modules: fuzzification, inference, defuzzification and evaluation. The inference process begins when each feedback error x_{tk} is mapped on fuzzy sets. Then, functions that map each linguistic state of x_{tk} to a state of y_t are synthesized based on MGGP principles. The crisp control signal is obtained through the defuzzification process. This solution is evaluated and then selection and recombination operators are applied. These steps are repeated until a stopping criterion is met. These four modules are described in details in the following sub-sections.

4.1 Fuzzification

Let x_{tk} and y_t admit J distinct linguistic terms, or fuzzy sets (j=1,...,J). These are defined by normalized and uniformly distributed membership functions [30]. Figure 4 presents an example of the fuzzification of the *k*-th plant output, with seven membership functions with the following linguistic terms: NB – Negative Big; NM – Negative Medium; NS – Negative Small; NZ – Near Zero; PS – Positive Small; PM – Positive Medium; and PB – Positive Big (in this case, j=1,2,...,7).

Figure 4. Example of membership functions

After fuzzification of each input x_{tk} , the GPFIS-Control inference process initiates.

4.2 Fuzzy Inference

The inference procedure consists of three stages: *Formulation*, *Partitioning* and *Aggregation*. In *Formulation* stage, t-norm, t-conorm, linguistic hedges and negation operators are defined. In *Partitioning* stage, the mechanism that connects each antecedent with a consequent is established. Finally, in *Aggregation* stage, operators used to combine all rules are defined.

4.2.1 Formulation

Through each $A_{jk}(x_{tk})$ (membership degree of x_{tk} to a fuzzy set A_{jk}), GPFIS-Control evolves a

Figure 2. Example of Multi-Gene Genetic Programming recombination operators

Figure 3. Block diagram of GPFIS-Control model

Figure 5. Uniform division procedure

Some examples of $g\left[f_{d\in s_1}\left(\mu_{A_{j1}}\left(x_{t1}\right),\ldots,\mu_{A_{jK}}\left(x_{tK}\right)\right)\right]$ are:

- $-g \rightarrow \max \left[f_{d \in s_1} \left(\mu_{A_{j1}} \left(x_{t1} \right), \dots, \mu_{A_{jK}} \left(x_{tK} \right) \right) \right]$: max aggregation operator are the most common used on Mamdani type FIS.
- $-g \rightarrow \frac{\sum_{i} \{d \in s_{j}\}}{card(s_{j})} [[f_{d \in s_{1}}(\mu_{A_{j1}}(x_{t1}), \dots, \mu_{A_{jK}}(x_{tK}))] :$ arithmetic mean operator intends to provide equal weights for each element of the rule set associated to the j-th consequent.

In [31], several aggregation operators are presented. It can be shown that t-norms and t-conorms are special cases of aggregation operators. In the experiments both the arithmetic mean and maximum operators have been used. Once the aggregation operators have been defined, it is possible to compute the membership degrees for different actions $\mu_{B_j}(y_t)$ taken by the controller. The defuzzified control signal y_t is then computed.

4.3 Defuzzification

Basically, a defuzzification method (center of gravity, mean of maximum, etc.) produces a crisp value that is an interpretation of the information contained in the output fuzzy set resultant from the inference process. In GPFIS-Control the height method is used:

$$y_t = \frac{\sum_{j=1}^J b_j \mu_{B_j}(y_t)}{\sum_{j=1}^J \mu_{B_j}(y_t)}$$
(4)

where b_j represents the center (location) parameter of each B_j . The maximum height method may be employed when the control signal assumes values in some finite set:

$$y_{t} = \frac{\sum_{j=1}^{J} \phi_{j} b_{j} \,\mu_{Bj}\left(y_{t}\right)}{\sum_{j=1}^{J} phi_{j} \mu_{Bj}\left(y_{t}\right)}$$
(5)

where ϕ_j is an indicator function, such that $\phi_j = 1$, when $\mu_{B_j}(Y_t) > \mu_{B_l}(Y_t)$, for all l=1,...,J, $e \ l \neq j$, $e \ \phi_j = 0$, otherwise.

Figure 6 presents an illustration of the difference between these procedures. We obtained: $\mu_{NM}(Y_t) = 0.8$, $\mu_{PZ}(Y_t) = 0.6$, while $\mu_{NG}(Y_t) = \mu_{NP}(Y_t) = \mu_{PP}(Y_t) = \mu_{PM}(Y_t) = \mu_{PG}(Y_t) = 0$.

Then, according to Eq. (4):

$$Y_t = \frac{-20 \cdot 0.8 + 0 \cdot 0.6}{0.8 + 0.6} = -11,43$$

If it was used maximum height method, the response would be -20, because the presence of only one maxima value. Height method provides a smoother transition between responses than maximum height.

4.4 Evaluation

The right definition of the fitness function is crucial for obtaining a good performance of the GPFIS-Control model. For optimal tracking of a trajectory, a possible fitness function is the Mean Squared Error (*MSE*):

$$MSE = \frac{1}{K} \sum_{k=1}^{K} (x_{tk})^2$$
(6)

When the *MSE* is minimized, the GPFIS-Control model successfully obtains a trajectory close to the setpoint. In minimum time problems, the fitness function may be the time (*t*) the output takes to reach an MSE $< \varepsilon$, where ε is a tolerance. GPFIS-Control tries to reduce the size and complexity of the rule base by employing a simple heuristic called Lexicographic Parsimony Pressure [33]. This technique is only used in the selection phase: given two individuals with the same fitness, the best one is that with fewer nodes. Fewer nodes indicate rules with fewer antecedents, hedge and negation operators, as well as few functions (f_d) , and, therefore, a smaller rule set.

After the evaluation procedure, a set of individuals are selected (using tournament procedure) and recombined. Then, in a subset of the population, the mutation (Figure 7a), low-level crossover (Figure 7b) or high-level crossover (Figure 7c) operators are applied. Finally, a new population is generated.

This process is repeated until a stopping criteria is met. At this moment, the final population is returned.

5 Case Studies

Two benchmark problems have been considered to evaluate the GPFIS-Control model: cartcentering [25,28] and inverted pendulum [9,12]. The cart-centering problem has been used to assess the performance of GPFIS-Control in comparison with other GFCs. The application to the inverted pendulum made use of the GPFIS-Control parameters obtained in the tuning for the cart-centering problem. Results were compared to those presented in [12].

5.1 Experimental Settings

5.1.1 Cart-centering Problem

The cart-centering problem consists of a cart with mass *m* moving on a frictionless rail; at some instant *t* its position is x_t (*m*), with velocity v_t (*m/s*). The cart must stop ($v_t = 0$) at a user-defined setpoint *ref*. Tolerance values ε may be considered, so that $|x_t - ref.| < \varepsilon$ and $|v_t - ref.| < \varepsilon$. The plant dynamics is given by Equations (7) and (8):

$$v_{t+\tau} = v_t + \tau \frac{F_t}{m} \tag{7}$$

$$x_{t+\tau} = x_t + \tau v_t \tag{8}$$

where τ is the sampling period and F_t is the force (N) applied by the controller to the cart at time t. The objective is to reach the setpoint in minimum time. The performance of GPFIS-Control has been compared to the GFC presented in [25]. Several configurations for GPFIS-Control (t-norms, aggregation operators, etc.) have been evaluated. To perform a fair comparison, configurations were the same as those in [25] for all variables and parameters (Table 2 displays these values).

GPFIS-Control is required to move the cart until $|x_t - 0| < 0.5$ and $|v_t - 0| < 0.5$, given 16 initial values uniformly distributed on the x_t domain. The fitness function has been defined as:

$$Fitness = t_{\varepsilon} + \sum_{t} |x_t| \tag{9}$$

where t_{ε} is the time needed to satisfy the stopping criteria ($|x_t - 0| < 0.5$ and $|v_t - 0| < 0.5$). An individual in the GPFIS-Control population is considered unfeasible if it cannot stop the cart in 10 seconds (500 sampling steps).

 Table 2. Configurations Set for Cart-Centering

After the best solution is found, it is applied to 1000 initial random positions in order to evaluate the time taken by GPFIS-Control to stop the cart. In order to perform a fair comparison with [25], the following procedure has been executed 10 times: (*i*) generate a GPFIS-Control model and, (*ii*) apply it on 1000 random position, in order to produce statistical relevant results. The best GPFIS-Control model is obtained, in each execution, after 25000 evaluations (population size = 50 and number of generations = 500, respectively). Table 3 displays all the parameters of the GPFIS-Control model.

5.1.2 Inverted Pendulum Problem

The second experiment consisted of an application of GPFIS-Control to the inverted pendulum problem. Results were then compared to those of [12]. In this problem, a cart of mass M with a pole of mass m and height λ attached to its center moves on a frictionless rail. The controller must apply F_t in order to increase or decrease v_t and consequently change the angular velocity ω_t and the pendulum angle θ_t . The dynamic model [12,28] is described below:

$$\phi_t = \frac{g \sin \theta_t + \cos(\theta_t) \Psi}{\lambda \left[\frac{4}{3} - \frac{m \cos^2 \theta_t}{M + m}\right]} \tag{10}$$

$$\Psi = \frac{-F_t - m\lambda\omega_t \theta_t^2 \sin \theta_t}{M + m}$$
(11)

$$\omega_{t+1} = \omega_t + \tau \phi_t \tag{12}$$

$$\theta_{t+1} = \theta_t + \tau \omega_t \tag{13}$$

$$a_t = \frac{F_t + m\lambda[\theta_t^2 \sin \theta_t - \omega_t \cos \theta_t]}{M + m}$$
(14)

$$v_{t+1} = v_t + \tau a_t \tag{15}$$

$$x_{t+1} = x_t + \tau v_t \tag{16}$$

where ϕ_t is the angular acceleration and τ is the sampling step. In order to perform a fair comparison with [12], the feasible domain for each

Figure 7. Example of recombination operators applied in GPFIS-Control solutions

variable was set as: $\omega_t \in [-0.87, 0.87] \text{ rad/s}$, $\theta_t \in [-0.34, 0.34] \text{ rad}$, $F_t \in [-25, 25] N$, while x_t and v_t are unconstrained, M=1kg, m=0.1kg, λ =0.5m, $g=9.8m/s^2$ and $\tau=0,01s$. Two initial conditions were considered: $\theta_0 = \{-0,18, 0,18\}$ rad, with $\omega_0=\{0,0\}$ rad/s and the setpoint is ref=0 rad with $\varepsilon=0.01$. The time allowed for the position $|\theta_t - 0| < 0.01$ to be reached is at most 1 second (100 sampling steps).

As in [12], 100,000 evaluations (population size = 100 and number of generations 1000) have been made. All this procedure was repeated 10 times, in order to generate statistical relevant results. Table 3 exhibits the remaining parameters used. The fitness function is [12]:

$$Fitness = \sum_{t=1}^{100} (\theta_t - ref)^2$$
(17)

In both experiments seven fuzzy sets have been assigned to each variable (F_t , x_t , v_t , ω_t , θ_t), as shown in Figure 4. In some cases, the negation of a fuzzy set was entered in the Input Fuzzy Sets stage of the GPFIS-Control routine (as described in section 4.2.1). All experiments were performed in MATLAB R2010a [34].

5.2 Results and Discussions

5.2.1 Cart-Centering Problem

The main results obtained with the cartcentering problem are presented in Table 4. GPFIS-Control was tested with the linguistic hedge square root, the classic negation operator, different aggregation operators (max and average) and different defuzzification methods (height and maximum height). It can be seen that for almost all configurations, the use of the average aggregation operator reduces by about 39% the mean time taken by the controller to position the cart at $|x_t - 0| < 0.5$ and $|v_t|$ -0 < 0.5. It may also be noted that the maximum height defuzzification reduces that time in 14% in average. However, the use of the negation operator does not incur in any substantial time decrease, although fewer rules are generated. In fact, the negation operator has a summarizing power, due to the enlargement of a fuzzy set support in the universe of discourse.

The best configurations were obtained with the following parameters: maximum height method for defuzzification and average as the aggregation operator. Figure 8 present the 16 initial and final positions when $|x_t - 0| < 0.5$ and $|v_t - 0| < 0.5$. Figure 9 exhibits the response surface for GPFIS-Control best configuration for (a): maximum height defuzzification method and (b): height defuzzification method. It can be seen that the surface for (b) is smoother than that for (a), due to a broader set of values that F_t can assume when the height method is chosen.

The average best result for GPFIS-Control (135.8 steps) compares favorably with those of [25] (158 steps) and [35] (149 steps). The optimal solution is 129 steps.

Figure 8. Initial and final position for the best individual in an execution of GPFIS-Control, using Product+Root-Sq+MaxHeight and average aggregation operator

5.2.2 Inverted Pendulum

Based on the best configuration previously established (Product + Root-Sq + Average + Max-Height), GPFIS-Control has been applied to the inverted pendulum problem. Figure 10 shows the controller's behavior, generated by the best individual in 100,000 evaluations, given two initial conditions: $\theta_0 = \{-0,18, 0,18\}$ rad, with $\omega_0 = \{0,0\}$ rad/s. The average best result found for GPFIS-Control was 0.27 seconds to reach and stay at $|\theta_t - 0| < 0.01$ during 1.00 second, generating 14 rules in average. In [12] the GFC took 0.61 seconds to perform the same task, however producing fewer rules (7 rules).

Figure 10. Initial and final position for the best individual in an execution of GPFIS-Control, using Product+Root-Sq+MaxHeight and average aggregation operator configurations

6 Conclusion

A novel approach for solving control problems has been presented. It consists of a Genetic Programming Fuzzy Inference System for Control tasks (GPFIS-Control), based on Multi-Gene Genetic Programming. The proposed GPFIS-Control model considers the usual stages of a Genetic Fuzzy Inference System: fuzzification, inference, defuzzification and evaluation.

The performance of GPFIS-Control has been evaluated through two benchmarks problems: cartcentering and inverted pendulum. The use of different aggregation, defuzzification and negation operators has been analyzed. It was shown that the right choice of defuzzification and aggregation operators improves results, while the use of negation may reduce the number of rules. When compared to other Genetic Fuzzy Controllers, GFPIS-Control has shown a better performance in average.

Future works shall consider other benchmark and real world problems, as well as new methods in formulation, partitioning and aggregation. For example, rules could be aggregated by using a weighted average, with adaptive weights for the rules during the controller operation. This could improve results with fewer rules. The use of others partitioning methods can also improve the performance, helping GPFIS-Control model to select the most promising rules for each consequent. A sensitivity analysis of some parameters (tournament size, maximum tree depth, etc.) would help to evaluate their influence on the final result.
