The ages of several Oligocene to Miocene sedimentary formations from the Eastern Carpathians Bend Zone are poorly constrained due to palaeoenvironmental factors, reworking of fossils, structural complexity and limited exposure. To help overcome these issues, this study integrates calcareous nannoplankton and foraminifera biostratigraphy with isotopic age dating (U-Pb) of volcaniclastic zircons, and sedimentological and structural observations/interpretations. Our study was carried out along an ~6-km-long section made from a series of outcrops along the Bizdidel River which exposes several formations such as the Pucioasa, Fusaru, Vineţişu, Starchiojd and Slon. We show that the Fusaru Formation consists of coarse-grained rocks deposited as confined longitudinal channel successions that migrated laterally. It is bounded by the mud-rich Pucioasa and Vineţişu formations which are lateral equivalents of the Fusaru confined channels deposited as levee/overbank units. These genetically related formations appear to reach younger ages – of the lower to middle Burdigalian based on calcareous nannoplankton and foraminifera biostratigraphy – than previously thought (upper Oligocene to lower Burdigalian). The dominant organic-rich mudstones of the Starchiojd Formation represent pelagites/hemipelagites deposited in anoxic conditions. Their middle Burdigalian age is established by a 17.41 ±0.27 Ma zircon U-Pb age of zircons from the Bătrâni Tuff in the Starchiojd Formation. Based on the similar phenocryst content, zircon U-Pb age and zircon trace element composition, the source of the tuff is suggested to be the 17.3 Ma Eger ignimbrite-forming eruption, which has proximal, near-caldera deposits in the Bükkalja Volcanic Field, Hungary. The mud-rich Slon Formation seems to be related to shelf edge/upslope failure that formed cohesive debrite avalanches resulting from foreland propagation of compression. The Slon Formation extends in this area to at least the upper part of the lower Miocene to middle Miocene. These results highlight the need to revise ages of those parts of the sequence which are poorly constrained or different in other parts of the Carpathian Basin. Such revised ages help to better constrain the understanding of the deformation history of the Carpathians.

Key words: biostratigraphy, tuff, zircon U-Pb age, sedimentology, structural geology.

INTRODUCTION

The specific tectonic and palaeoenvironmental conditions operating during the Oligocene to Miocene in the Eastern Carpathians Bend Zone (ECBZ; Fig. 1) has led to limitations in assigning the relative ages of several formations. Traditionally considered Oligocene to lower Miocene (Mărunţeanu, 1999; Melinte and Brustur, 2008; Melinte and Stoica, 2013), recent studies carried out in the ECBZ revealed that at least locally some formations may be younger, up to the middle Miocene; Tămaş, 2018; Filipescu et al., 2020).

One problem in this area is the extensive reworking (Szabo, 2012), hence the traditional biostratigraphy rarely provides reliable markers. However, locally, calcareous nannoplankton and foraminifera may give useful biostratigraphic clues, especially when long sections are available.

More reliable stratigraphic data and information may be obtained by combining the biostratigraphy and sedimentology with radioisotopic data, all analysed in a structural context. Also, by doing this, some lithostratigraphic units can be re-interpreted as contemporaneous equivalents, rather than as successive units.

The presence of a ~6 kilometres long mildly deformed section at Pucioasa, along the Bizdidel Valley (Fig. 2A), where several formations crop out (Pucioasa, Fusaru, Vineţişu, Starchiojd and Slon; Fig. 3) created the opportunity for a re-interpretation of the stratigraphy and depositional environments. Moreover, the occurrence of a volcanic tuff intercalation (Bătrâni Tuff, Ştefănescu et al., 1993) in a regionally developed unit (Starchiojd Formation) proved to be of great help for stratigraphic calibration, by using zircon U-Pb age dating. The source area for the tuff based on petrology, zircon age dating and trace element composition is also discussed.

Our results, including more precise formation ages and a revised depositional environment for the Miocene deep marine formations, will better help to constrain the stratigraphy, tectonic deformation and palaeoenvironments of the Carpathians.

GEOLOGICAL SETTING

STRUCTURAL OVERVIEW

The Carpathians have a highly arcuate orogen shape (Fig. 1A) due to their palaeogeographic evolution in relation to the European/Moesian platforms, and Tisza, Dacia and Alcapa continental megablocks (Schmidt et al., 2008).

Following an extensional phase between the Triassic and early Cretaceous (Săndulescu, 1984, 1988), the tectonic history of the Carpathians is characterized by subsequent compressional deformation (Săndulescu, 1988; Hippolyte and Săndulescu, 1996; Maţenco and Bertotti, 2000; Leveer et al., 2006).

The overall thrusting implies a foreland propagating sequence (Maţenco and Bertotti, 2000) that formed a general eastwards (i.e. Eastern Carpathians) and southwards (i.e. South Carpathians) verging nappe system (Schmidt et al., 2008). The ECBZ (Fig. 1B) represents the transition between these two systems (Leveer et al., 2006). Based on the age and style of deformation (thin vs. thick-skinned; Săndulescu, 1984), different nappes have been described (see Săndulescu, 1984; 1988; Fig. 1C). The thick-skinned nappes consist of pre-Alpine basement rocks, metamorphosed during the Paleozoic (Kraütner and Bindea, 2002; Medaris et al., 2003; Balintoni et al., 2014; Ducea et al., 2016) and Cretaceous sedimen-

tary/magmatic formations thrusted during the Early and Late Cretaceous (Săndulescu, 1984; Fig. 1B, C). The Cretaceous to middle Miocene sequence among the thin-skinned nappes thrusted during the late Paleogene to middle Miocene (Săndulescu, 1988; Răbăgia et al., 2011; Fig. 1B, C). The Tarcău Nappe, which represents the subject of our study, was considered to be emplaced from the early Miocene, with an intra-Burdigalian onset (Săndulescu 1984; Merten et al., 2010) or probably even later (middle Miocene; Filipescu et al., 2020). Also, Schleder et al., (2019) suggested that some folding/thrusting and erosion took place during the intra-Burdigalian phase in the proximal part of the Tarcău Nappe (Fig. 1D). The compression continued towards the foreland (Maţenco and Bertotti, 2000; Merten et al., 2010) mostly in a piggyback setting (e.g., Valea Lungă Syncline, Fig. 1D; Bercea et al., 2016; Tămaş, 2018; Schleder et al., 2019). The latest deformation (the Wallachian phase – Meotian to Recent; Hippolyte and Săndulescu, 1996) that affected the ECBZ was related to crustal-scale shortening through the reactivation of basement faults and produced uplift/erosion of 4–5 km (Sanders et al., 1999; Merten et al., 2010). This phase was characterized by minor deformation under N–S compression. The Wallachian structures are represented by gentle to open folds (Hippolyte and Săndulescu, 1996; Schleder et al., 2019).

STRATIGRAPHY AND PRE-EXISTING AGE CONSTRAIN

The Tarcău Nappe consists of Cretaceous to middle Miocene formations. Two different lithofacies have been defined for the deep marine Oligocene to lower Miocene deposits of the Tarcău Nappe of the ECBZ (Conţescu et al., 1966; Sylvester and Lowe, 2004; Răbăgia et al., 2011; Szabo 2012): an internal one, of Carpathian origin, of Pucioasa-Fusaru facies, and an external one, of foreland origin (non-Carpathian), with a bituminous facies and Kliwa-type sandstones (Săndulescu et al., 1995); an interbedded zone exists between the two lithofacies (Pătruţ, 1955).

The lower Oligocene started in the ECBZ with the deposition of dark-coloured organic-rich shales/bituminous menilites of the "lower dysodiles"/"menilites" (Olteanu, 1952; Popescu, 1952; Melinte and Brustur, 2008). The Pucioasa and Fusaru formations (Mrazec and Popescu-Voiteşti, 1914; Olteanu, 1952; Pătruţ, 1955) were considered as late Oligocene (NP24-NP25) based on the presence of *Pontosphaera enormis*, *Triquetrorhabdulus carinatus*, *Sphenolithus conicus* and *S. delphix* calcareous nannoplankton (Vineţişu Valley – ECBZ; Melinte and Brustur, 2008). The Pucioasa-type deposits consist of dark grey massive/laminated calcareous mudstones, rare organic-rich mudstones (Pătruţ, 1955) with thin cross/planar-laminated very fine- to fine-grained sandstones and siltstones (Szabo, 2012; Frunzescu, 2013) as well as rare thin coccolithic limestones (Melinte and Brustur, 2008). The Fusaru deposits consist of subgreywacke, quartzo-feldspathic calcareous sandstones, conglomerates/breccias and mudstone intercalations. They are embedded in the Pucioasa Formation (Ştefănescu et al., 1988; Săndulescu et al., 1995; Sylvester and Lowe, 2004; Szabo, 2012). The Pucioasa facies was first described by Mrazec and Popescu-Voiteşti (1912 *fide* Pătruţ, 1955) and the Fusaru facies by Popescu-Voiteşti (1910 *fide* Ştefănescu, 1995) from around the town of Pucioasa. In the Eastern Carpathians, north of the area investigated, based on the presence of the foraminifer *Globoquadrina dehiscens* (Tarcuţa River, northern part of the Eastern Carpathians) in the mudstones of the Fusaru Formation, an age of not older than Aquitanian was assigned (Belayouni et al., 2007). A Fusaru-like
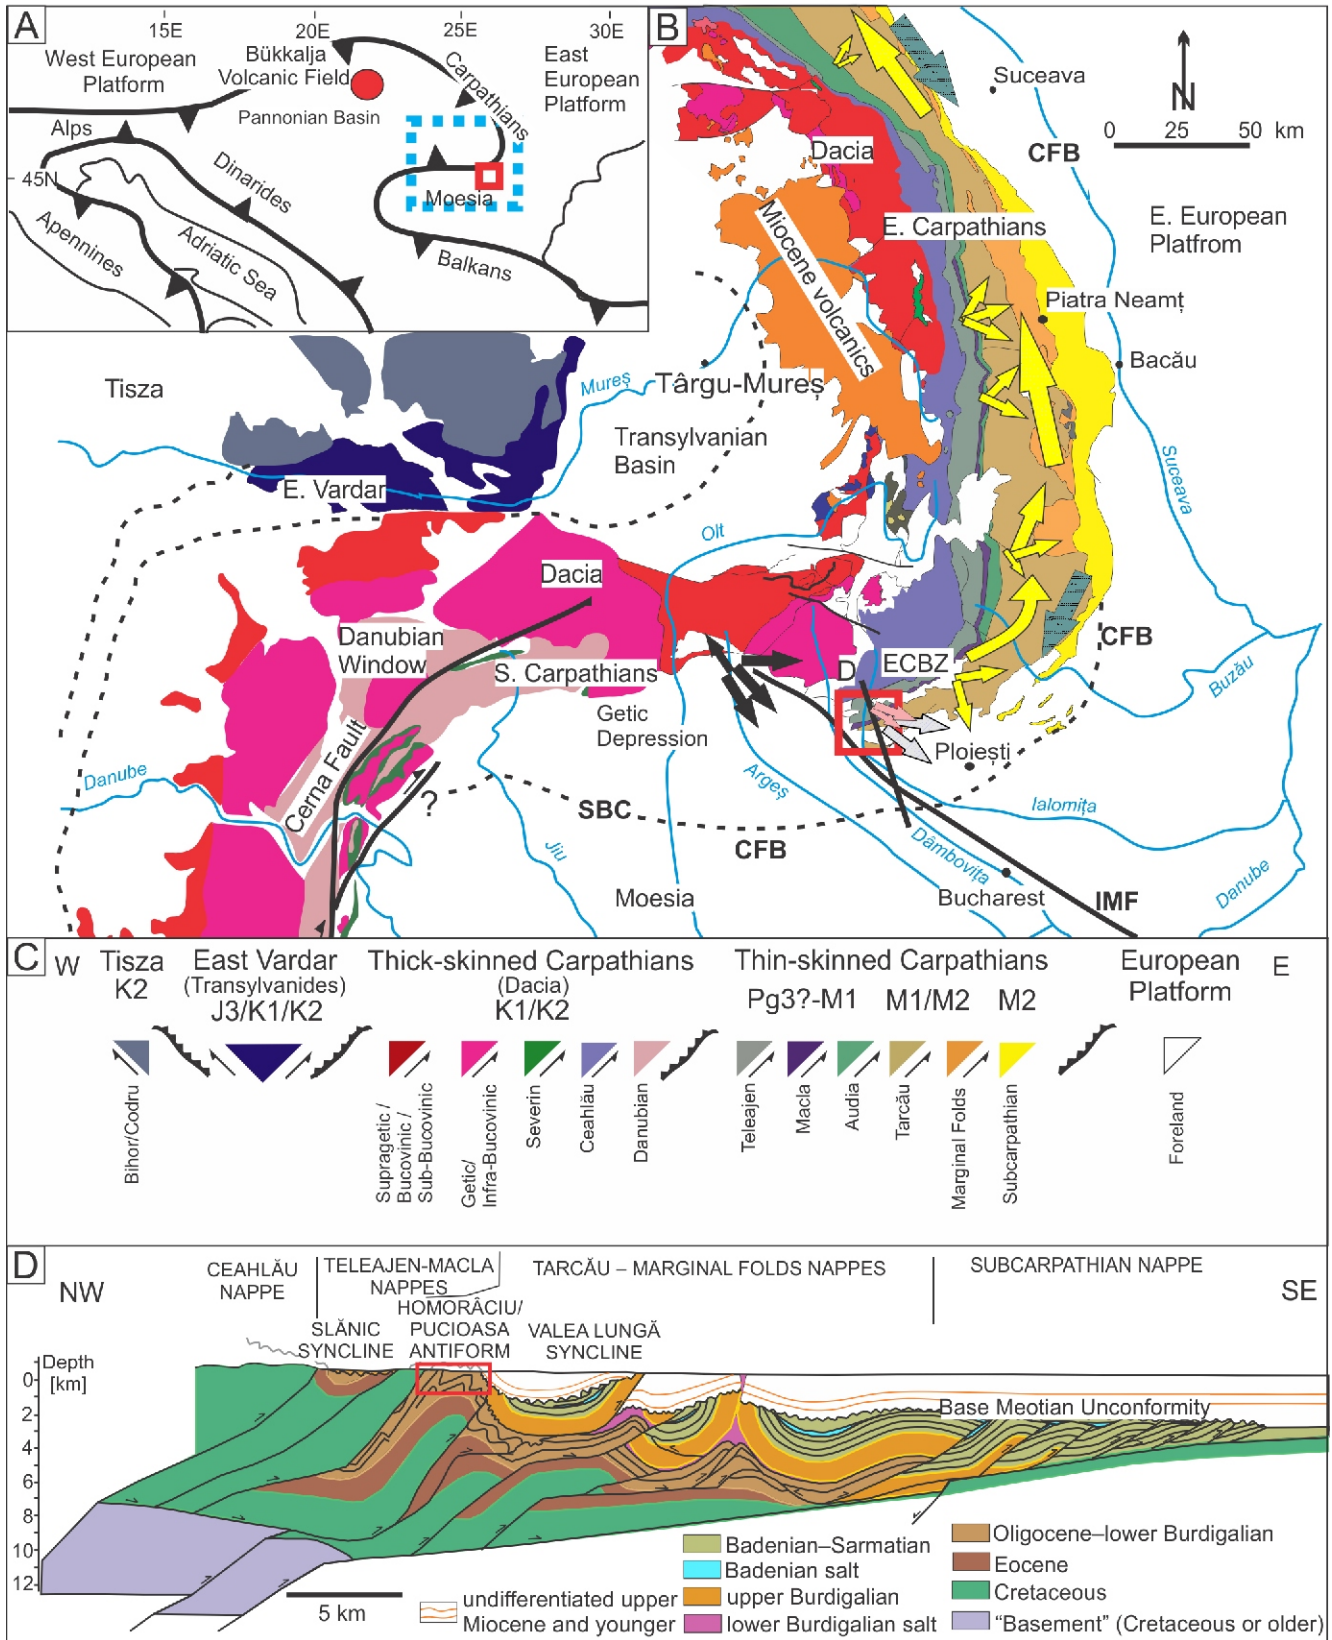

Fig. 1A – location of the Romanian Carpathians within the Alpine-Carpathian belt (Krézsek et al., 2013); red circle = Bükkalja Volcanic Field; dashed blue rectangle – Fig. 1B; red square – area of interest; B – tectonic sketch of the Romanian Carpathians (modified from Krézsek et al., 2013 based on Săndulescu, 1988; Bădescu, 2005; Schmid et al., 2008), red square – area of interest, arrows – palaeocurrent directions (p.d.) from different formations (Conţescu et al., 1966), black arrows – p.d. for the Corbi/Cheia formations (Jipa, 1982; 1994 *fide* Roban, 2008), pink arrows – p.d. from Fusaru deposits (this study), SBC – subsurface Subcarpathian Nappe, CFB – Carpathians Foredeep basin, IMF – IntraMoesian Fault, ECBZ – Eastern Carpathians Bend Zone; C – nappes of the Romanian Carpathian area. Age of deformation: J3 – Late Jurassic, K1 – Aptian–Albian, K2 – late Campanian–early Maastrichtian, Pg3?-M1 – (?)late Oligocene–early Burdigalian, M2 – middle Miocene (Răbăgia et al., 2011; Krézsek et al., 2013); D – modified regional cross-section from Schleder et al. (2019)

petrofacies (i.e. Cheia, Corbi formations) was also observed in the eastern Getic Depression (Roban, 2008; Fig. 1B). Răbăgia et al., (2011) considered that this facies migrated in time (early to late Oligocene) and space (from the Getic Depression towards the ECBZ and EC), being embedded within Pucioasa-like mudstones (i.e. Brăduleţ Formation in the Getic Depression) due to compression from the propagating foreland. Recently, Miocene foraminifera (e.g., *Trilobatus quadrilobatus, Globoquadrina dehiscens*) and calcareous nannoplankton (e.g., *Sphenolithus belemnos, Helicosphaera ampliaperta*) assemblages were identified by Szabo et al., (2010) and Szabo (2012) in the Pucioasa and Fusaru formations along the Pucioasa section (Fig. 2A, B).

The Vineţişu Formation (Grigoraş,1951 *fide* Popescu, 1952; Melinte and Brustur, 1998) consists of grey calcareous mudstones and some centimetre/metre-thick bentonitic tuffs (Vineţişu/Gura Vitioarei bentonites, Vălenii de Munte/Mlăcile tuffs), (Ştefănescu et al., 1993; Alexandrescu et al., 1994; Frunzescu, 2013; Fig. 3) with interbedded thin convolute fine-grained and bioturbated sandstones (Popescu, 1952; Szabo, 2012). Based on calcareous nannoplankton, this formation was considered uppermost Oligocene to lower Burdigalian (NP25–NN2) (Vineţişu, Lupa and Teleajen valleys – ECBZ; Mărunţeanu, 1999; Melinte and Brustur, 2008).

The following "upper dysodiles" and "menilites" (Olteanu, 1952; Bădescu, 2005) or Starchiojd Formation (Popescu, 2002 *fide* Frunzescu, 2013) consist of dark grey organic-rich shales (dysodiles) with some menilites and decimetre/metre-thick argillitized volcanic tuffs such as the Bătrâni Tuff (Popescu, 1952; Ştefănescu et al., 1993; Fig. 3). This formation is considered lower Burdigalian (Mărunţeanu, 1999), as it is placed between the Vineţişu Formation (NN2 Biozone) and Cornu Formation (NN3 Biozone).

The Slon Formation (Popescu, 1961 *fide* Bucur, 1966; Săndulescu et al., 1995) was considered Oligocene to lower Burdigalian (Ştefănescu, 1995) based on the type of facies which developed in the Vineţişu, Starchiojd and Cornu formations (Olteanu, 1952; Ştefănescu et al., 1988; Ştefănescu, 1995; Frunzescu, 2013; Fig. 3). This facies is characterized by chaotic deposits with reworked Cretaceous, Paleogene and lower Miocene age clasts embedded in a black/grey mudstone interpreted as olistostromes (Ştefănescu, 1995) and developed in the ECBZ (Olteanu, 1952) and EC (Joja, 1952). Ştefănescu (1995) described thick (100 m), massive, convolute sandstones with fine conglomerates in the upper part of the Fusaru Formation and suggested that these replace the Pucioasa-Fusaru facies towards the hinterland.

The deep marine setting was replaced by a shallow marine setting during the early Burdigalian (Schleder et al., 2019). This can be observed through the presence of the shallow marine Cornu Formation with the Sărata Gypsum that has an erosional contact with the top of the deep marine Pucioasa-Fusaru lithofacies (Mrazec and Popescu-Voiteşti, 1914; Mărunţeanu, 1999; Schleder et al., 2019; Filipescu et al., 2020; Fig. 3). These are followed by the unconformable Burdigalian–lower Badenian coarse-grained deltas of the Doftana Formation (*sensu* Ştefănescu and Mărunţeanu, 1980; Mărunţeanu, 1999). Recently, Filipescu et al. (2020) suggested that the Cornu and Doftana formations may be in reality younger (upper Badenian to Sarmatian).

METHODS

An ~6-km-long section with a series of exposures at Pucioasa (Fig. 2A) along the riverbed and riverbank of the Bizdidel Valley (N 45°5'45.80", E 25°26'51.99") was analysed by biostratigraphic, radiometric (zircon U-Pb dating on the Bătrâni Tuff), structural and sedimentological methods. The formations utilized in this study are based on the 1:50,000 Pucioasa map of Ştefănescu et al. (1988; Fig. 2A).

FIELDWORK AND SAMPLE COLLECTION

Detailed structural and sedimentological field observations and measurements of bedding, faults, fractures, folds and palaeocurrents were recorded. The structural measurements were taken using both a 360° Freiberg compass/clinometer and the *FieldMove™* digital mapping application. The sense of fault movement was determined based on the presence of offset stratigraphic markers or kinematic indicators such as slickenlines or slikenfibres. Fault-slip slickenline data were collected *in situ* from exposed fault surfaces in order to perform a palaeostress inversion. In this study, the fault data were analysed using Angelier's (1990) direct inversion method (INVD) implemented in *SG2PS* software (Sasvari and Baharev, 2014). This method estimates the reduced stress tensor and the shear stress magnitudes from fault-slip data (Angelier, 1990). The program also graphically computes the stress regime based on the stress index (*R'*; Delvaux et al., 1997). Structural data processing and visualization were carried out using *Stereonet 10* (Allmendinger et al., 2012; Cardozo and Allmendinger, 2013). The measurements were graphically represented using both rose diagram plots of azimuth distributions (at 10° sector angles) and equal area stereonets, lower hemisphere projection using poles to planes where appropriate. The contouring was calculated after Kamb (1959) at 2 and 3 sigma standard deviation above a random population.

The cross-section was constructed in *Move* software suite following successive steps which includes: georeferencing and importing the 1:50,000 geological map of Ştefănescu et al. (1988), preexisting cross-sections (e.g., Stefanescu et al., 1988; Bercea et al., 2016; Schleder et al., 2019) and the Digital Elevation Model of the area. The structural measurements from the field (collected with coordinates) were also imported in the project and projected onto the cross-section. The next step involved the construction of the cross-section using all the data. In Move, we mainly used a tool called "horizon" from a template which allows the construction of the layers by keeping the thickness constant. The sedimentological data was obtained at centimetre/decimetre scale and included grain size (10x hand lens, Wentworth grain size comparator, ruler), lithology, bed contacts and sedimentary structures. The sedimentological data was grouped into facies and facies associations. Four synthetic logs were made starting from the two major anticline hinge lines having a thickness ranging from ~350 to 800 m. A 1 m Jacob staff with a 360° Freiberg compass was used for the thickness measurements. Quantitative palaeocurrent measurements were obtained and plotted in *SG2PS* (Sasvari and Baharev, 2014) software (modified in *CorelDraw2022*) although not re-tilted for tectonic dip correction (bedding dip <= 20°; Collinson et al., 2006). Also, 3 qualitative palaeocurrent (no dip correction) observations were made to ascertain the gross direction of flow for some asymmetrical ripples (Vineţişu Formation).

BIOSTRATIGRAPHY

The biostratigraphy was interpreted based on calcareous nannoplankton and foraminifera. Forty-one mudstone samples from the Pucioasa section (Fig. 2A) were analysed for calcareous nannoplankton content. The samples were prepared by the standard smear slides technique (Bown and Young, 1998) and examined under a light microscope (Axiolab A) in polarized
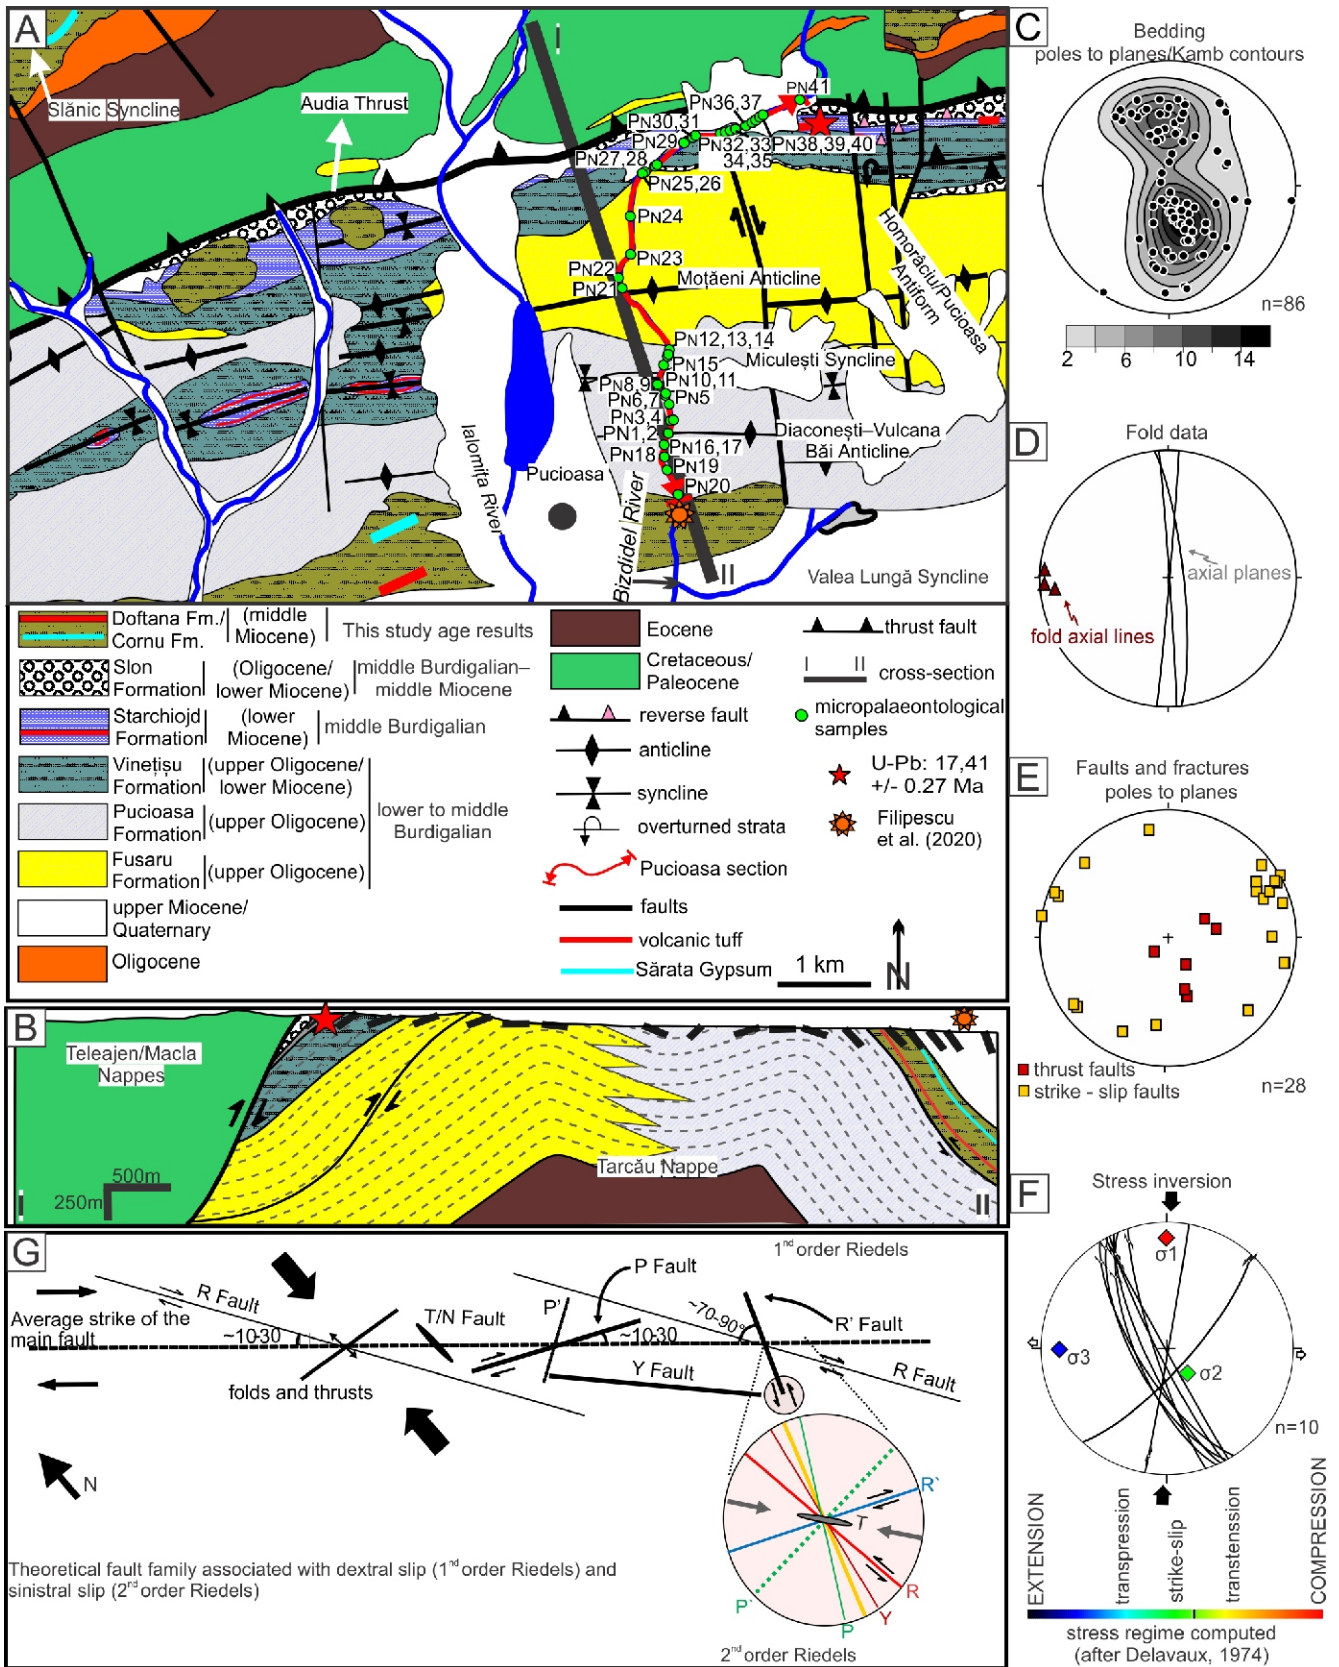

Fig. 2A – 1:50,000 modified geological map of the Pucioasa area (Ştefănescu et al., 1988); B – simplified cross-section using sur-
face and subsurface published data (Ştefănescu et al., 1988; Schleder et al., 2019); C–E – stereonets of structural data collected in
the field; F – stress inversion plot (after Angelier, 1990) of fault lineation data; G – theoretical fault family associated with dextral
(1st order) and sinistral slip (2nd order; adapted after Carne and Little, 2012)

Calcareous nannoplankton biozones based on Martini (1971) while the age distribution is from Raffi et al. (2020). Burdigalian division is based on Grunert et al. (2010). Lithostratigraphy uses information from Ştefănescu et al. (1988, 1993, 1995); Mărunţeanu (1999); Bădescu (2005); Melinte and Brustur (2008); Popescu (2002), *fide* Frunzescu (2013), Filipescu et al. (2020); UD/M – upper dysodiles and menilites. Discontinuous dotted red lines represent regional tuffs in the ECBZ/Eastern Carpathians: TVi (Vineţişu Tuff), GVb (Gura Vitioarei bentonites), TVa (Vălenii de Munte Tuff), TMl (Mlăcile Tuff), TB (Bătrâni Tuff), TF (Falcău Tuff; Ştefănescu et al., 1993; Alexandrescu et al., 1994; Frunzescu, 2013). Red star: UPb dated Bătrâni Tuff = 17.41 ±0.27 Ma. Depositional environment based on Conţescu et al. (1966), Ştefănescu (1995), Sylvester and Lowe (2004), Szabo (2012), Bercea et al. (2016), Schleder et al. (2019)

light, at 1000 x magnification. Biostratigraphic and palaeoeco-logical information provided by foraminifera was interpreted us-ing the material of Szabo (2012).

ZIRCON U-Pb DATING AND ZIRCON TRACE ELEMENT ANALYSIS OF THE BĂTRÂNI TUFF

U-Pb dating of the Bătrâni Tuff was done after separating zircons by heavy liquid density-based and magnetic methods from the 63–250 µm fractions. The zircon grains were mounted in 1" epoxy resin and polished to a 1 µm finish. Before dating, the zircons were checked with optical microscopic and cathodoluminescence imaging. Cathodoluminescence imaging was produced using an *AMRAY 1830* SEM equipped with *GATAN MiniCL* and 3 nA, 10kV setup at the Department of Petrology and Geochemistry, Eötvös University in Budapest. The *in situ* zircon U-Pb isotopic and simultaneous trace element analyses were performed at the Department of Earth Sciences, ETH Zürich by laser ablation single-collector sector field inductively coupled plasma mass spectrometry (LA-SF-ICP-MS). Further instrumental, setup and data processing information are given in supplementary Appendices 1 and 2. Validation reference materials, covering an age interval between 1063.5 Ma and 2.409 Ma, were used to correct the matrix-dependent age offsets after Sliwinski et al. (2017). The average precision of the reference materials ranged from 1.2% to 2.3% (2se) in the case of secondary RM older than 30 Ma, while the youngest has 8.3% (2se) average precision. The Th disequilibrium correction was performed after alpha dose-correction assuming a constant Th/U partition coefficient ratio of 0.33 ±0.063 (1 ; Rubatto and Hermann, 2007) and using the equations of Schärer (1984). Zircon U-Pb dates were not corrected for common Pb contents; however, during data reduction, integration intervals were set to exclude the common Pb-contaminated signal intervals and data were filtered according to their discordance ($[(^{207}Pb/^{235}U\ Age) - (^{206}Pb/^{238}U\ Age)] / (^{207}Pb/^{235}U\ Age) < 10$ %). Average uncertainty of the individual zircon dates is given as 2se and is 1.74% (rse). In the case of trace element analysis, we used NIST610 as primary reference material and zircon 91500 for quality control, and an in-house synthetic reference material (Synthetic Zircon Blank) to correct the Nb concentrations. Target elements were Si, Zr, REE, Y, Hf, P, Nb, Ta, U, Th, Ti (see Appendix 2), and Al, Ba were measured for monitoring glass and apatite inclusions. Si (15.2 wt.% in zircon) was used as an internal standard for data reduction done by IOLITE. Spot compositions contaminated with inclusions based on elevated Al, Ba and La contents were discarded from the interpretation.

RESULTS

The Pucioasa section is ~6 kilometres long and it extends between the Audia Thrust to the north and the northern margin of the Valea Lungă piggy-back syncline to the south (Fig. 2A). This section is along part of the Homorâciu anticline which is considered a major S/SSE-verging anticline, plunging to the west (Fig. 2A) and extending for at least 85 kilometres towards the east (e.g., Murgeanu et al., 1968). The Bizdidel River cuts the stratigraphy almost perpendicular to the structure of the Homorâciu/Pucioasa Antiform. The rocks exposed belong predominantly to the Fusaru, Pucioasa, and Vineţişu formations, with limited exposure of the Slon and Starchiojd formations to the north (Fig. 2A, B).

STRUCTURAL AND SEDIMENTOLOGICAL ASPECTS

STRUCTURAL STYLE

Close to the Audia Thrust, the beds dip generally moderately to steeply (~45 to 84°) to the N/NNW, and are highly deformed by closely spaced thrusts (a few metres apart) showing several repetitions of different formations. These thrusts most likely represent small-scale splays of the main Audia Thrust.

Away from the Audia Thrust, the beds typically dip gently to moderately (15–20°) to the N/NNW and S/SSE (Fig. 2B, D) and are deformed into large- (hundreds of metres) to small-scale (decimetre to metre) folds. Two large-scale anticlines (~1.6 kilometres wavelength), namely the Moţăeni and Diaconeşti-Vulcana Băi anticlines (Fig. 2A, B; Murgeanu et al., 1968), are separated by a syncline named here the Miculeşti Syncline (Fig. 2A, B). These folds are upright (axial plane 80–89°), gentle to open structures (interlimb angles of ~120–130°) and plunge shallowly (1–10°) towards the W (Fig. 2C). These folds are inferred to detach on top of the Eocene and be underlain by imbricate units of Eocene and Cretaceous rocks (Schleder et al., 2019; Fig. 1D). This structure is also called the Pucioasa Antiform (Fig. 2A; Schleder et al., 2019). Smaller-scale folds (some of chevron type) of similar orientation to the large-scale structures are encountered locally (Fig. 4A).

The sequence is cross-cut by numerous shallowly-dipping thrust planes to high-angle faults and fractures with multiple orientations and kinematics (e.g., Figs. 2F and 4B–F). The shallowly dipping (12-39°) thrust planes are NNW–SSE- and WSW–ENE-trending (Fig. 2F). The NNW–SSE-trending thrusts generally display kinematic indicators such as slickenline lineations showing reverse (slightly) oblique kinematics suggesting top-to the NNE movements (Fig. 4B). The WSW–ENE-trending thrusts generally display top-to-the-S movements (Fig. 2D). However, in the forelimb of the Diaconeşti-Vulcana Băi Anticline, a hinterland-verging thrust was encountered. The displacement on these thrusts is generally difficult to assess due to the lack of stratigraphic markers; however, some thrusts show displacements of only a few centimetres to ~1 metre (e.g., Fig. 4C).

The high-angle faults (57–98°) have two main trends (Fig. 2F): NNW–SSE and NNE–SSW. The NNW–SSE -trending faults dip steeply towards the WSW (Fig. 2F). Some of these faults, generally the smaller-scale ones, show tip-damage patterns such as horsetail splay structures, consistent with dextral slip (Fig. 4B; e.g., Kim and Sanderson, 2006). In addition, fault planes generally preserved slickenlines also suggesting dextral kinematics (Figs. 2F and 4F). These faults are sub-parallel with the previously mapped large-scale N–S- to NNW–SSE-trending dextral faults which offset the fold structures by up to ~300 m, to the east of the study area (Fig. 2A) (Ştefănescu et al., 1988).

The NNE–SSW-trending faults dip steeply towards the WNW (Fig. 2F). Some of these faults are associated with wide (~1 m) damage zones dominated by a network of closely spaced (centimetre to decimetre) fractures (Fig. 4D). These fracture populations are consistent with a sinistral strike-slip Riedel system (Fig. 2G). Moreover, some of these faults often preserved slickenlines on their fault planes consistent with sinistral slip (Fig. 4E). Locally, these high-angle strike-slip faults seem to crosscut the NNW–SSE- trending thrusts (Fig. 4G).

Those two sets, dextral and sinistral, developed at ~60° to each other, can represent first-order Riedel shear structures
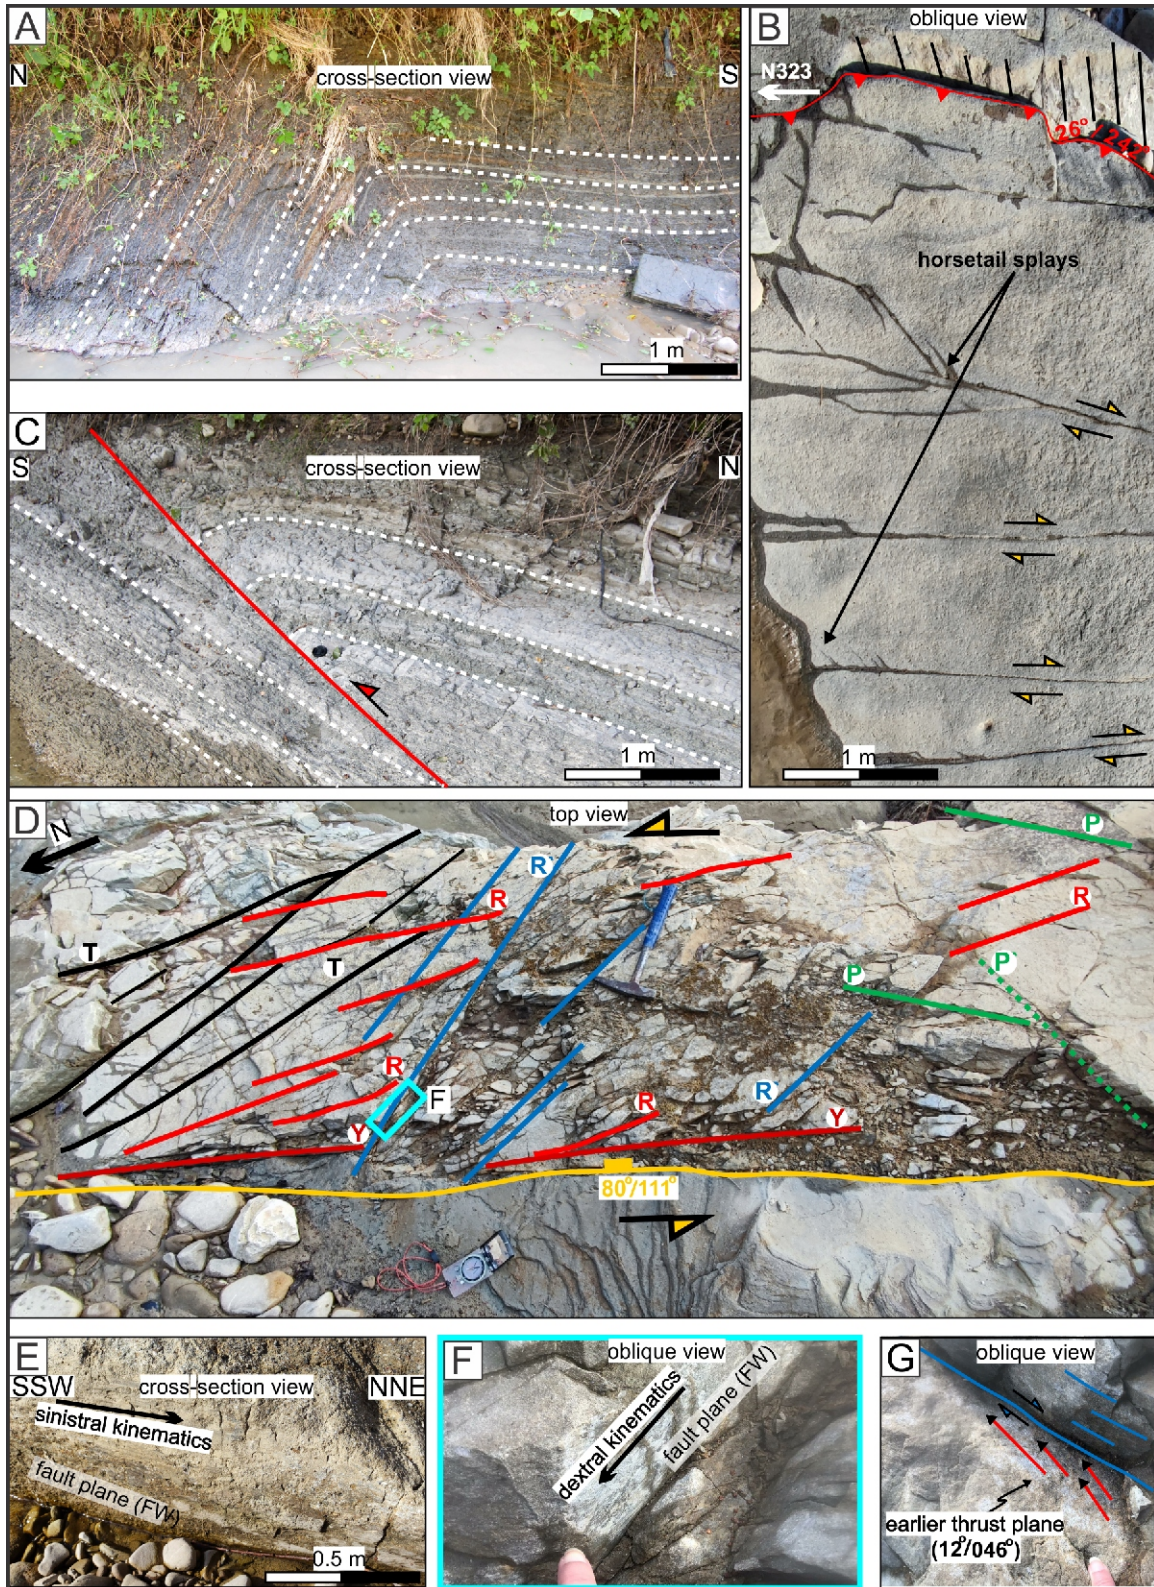

Fig. 4A – small-scale fold found close to the hinge line of the Diaconeşti-Vulcana Băi Anticline; B – horsetail splays with a thrust showing top-to-the-NNE movement (around Moţăeni Anticline); C – thrust with ~1 metre displacement (northern limb of Moţăeni Anticline); D – fractures related to a sinistral strike-slip Riedel system (Moţăeni Anticline); E – fault plane with slickenlines related to sinistral kinematics (Moţăeni Anticline); F – fault planes with dextral kinematics (Moţăeni Anticline); G – high-angle strike-slip faults that cross-cut the NNW–SSE-trending thrusts (Moţăeni Anticline)

developing simultaneously, as part of the same dextral strike-slip system (Fig. 2G). Palaeostress inversion analysis of these fault slip data yields a N-S compressive stress (Fig. 2F). The inversion suggests that the faults developed in a strike-slip to transtensional regime of near-horizontal compressive stress (1) with an axis orientated 16/002° and near-horizontal extensional stress (3) with an axis orientated 12/268° (Fig. 2F).

The N–S-directed compressive stress obtained is the same as the stress field suggested for the Wallachian phase (Hippolyte and Săndulescu, 1996). This stress field would also favor the development of the E–W-trending folds and the WSW–ENE-trending thrust (Fig. 2G). In addition, it is known that Wallachian folds present in the upper Miocene–lower Pleistocene strata are commonly large (interlimb angles of ~70–150°; Hippolyte and Săndulescu, 1996). Although developed in older stratigraphy, the folds observed in our study area are also gentle to open structures (interlimb angles of ~120–130°). It is very possible that these structures developed during the Wallachian phase together with the NNW–SSE-trending dextral faults (and associate Riedel shear structures) acting as tear faults which partitioned the E–W to WSW–ENE-trending contractional structures.

The NNW–SSE-trending thrusts identified in the study area (Fig. 4B, G) are more particular and do not seem to fit with the previously described (possibly) Wallachian structures. These thrusts, which are almost perpendicular to the E–W-trending folds and thrusts, are cross-cut by the high-angle strike-slip faults (Fig. 4G), suggesting their earlier development. It was previously suggested that the onset of deformation of the Tarcău Nappe, including the folds in the study area (Schleder et al., 2019), took place during the intra-Burdigalian phase (Săndulescu, 1984). It is possible that these structures are related to the pre-Wallachian events (intra-Burdigalian or Badenian-Sarmatian). A further regional study should be carried out to determine the nature and timing of these structures.

SEDIMENTOLOGY

The deposits analysed consist of several lithologies including mudstones, sandstones, slightly muddy sandstones, muddy sandstones, sandy to clast-supported conglomerates/breccias, muddy sandy conglomerates, muddy mud-clast conglomerates, volcanic tuffs, and organic-rich shales (dysodiles). They are associated with various sedimentary structures resulting in the description of 14 facies (F; Table 1). Those facies are grouped into 4 facies associations discussed below:

FACIES ASSOCIATION 1 (FA1): MUDSTONES WITH THIN- TO THICK-BEDDED SANDSTONES

The Pucioasa and Vineţişu formations (Figs. 2A, 3 and 5A1–A4) are characterized by F1 with thin-bedded very fine/fine sandstones (Fig. 6A–C) embedded in centimetre/metre thick dark/light grey (rare brownish/greenish) massive, laminated, graded mudstones (F2, Fig. 6D). Black organic-rich laminae are common in the mudstones. The sandstones are normally graded, have planar laminations, and asymmetrical and climbing ripples (Fig. 6A), with frequent muddy material on the foresets. The asymmetrical and climbing ripples can pass laterally/upwards into convolute lamination (Fig. 6C). Phytodetritus is frequent in the sandstones, the bases of which can be erosional to sharp. Rare centimetre-scale synsedimentary faults were observed. The medium-bedded muddy sandstones (F.3; Fig. 6E) and medium- to thick-bedded sandstones (F4; Fig. 6B, F) range from 10 to 80 cm-thick. The medium-bedded muddy

very fine to fine sandstones (F3) are convolute with water escape structures and can have flat, erosional bases with mud rip-up clasts. F4 medium- to thick-bedded sandstones are normally graded, amalgamated with erosional to sharp bases and with asymmetrical ripples, convolutions and planar laminae. The latter can contain plenty of coalified phytodetritus (Fig. 6F). Thin structureless sandstone intrusions (F5) develop along fractures and appear as sill/dyke composites (Fig. 6G) and dykes (Fig. 6B).

Interpretation: the above-described deposits were deposited by low-density turbidity currents (F1+F2+F4; Tce, Tde, Tcde, Tbce; Bouma, 1965), high- to low-density turbidity currents (F4; Tabce) and slurry flows (F3; Lowe and Guy, 2000). F1 is characterized by grain-size breaks (bypassed sediments, Talling et al., 2012) and plenty of distal asymmetrical climbing ripples (high suspended fallout rates) deposited in non-uniform flows (Jobe et al., 2011). The closeness of FA1 to the confined coarse-grained depostis belonging to the Fusaru channel successions (discussed in detail below) (Fig. 5A1–A4) can explain the above structures through a gradient change when flow stripping occurred because of a lack of confinement. Also, the lateral/upwards change of traction sedimentation into convolute laminae shows a rapid and active sedimentation environment (Talling et al., 2012; Tinterri et al., 2016). The sandstone slurry deposits are transitional flows where turbulence was diminished by mud content (Lowe and Guy, 2000; Hubbard et al., 2009). Lofting deposits (Zavala and Arcuri, 2016; Fig. 6F) may reflect extrabasinal hyperpycnal flow together with the graded mudstones and coalified phytodetritus. We interpret FA1 as a deep marine levee/overbank (F1, F2) setting with overbank elements such as crevasse splay lobes (F3, F4; Fig. 7; Hubbard et al., 2009). We interpret the structureless sandstone intrusions as post-depositional injectites over pressured fluidized sandstones (Duranti and Hurst, 2004) that may relate to a contractional regime as found elsewhere in the ECBZ (see Tămaş et al., 2020).

FACIES ASSOCIATION 2 (FA2): CONFINED SANDSTONES AND CONGLOMERATES

This represents the Fusaru Formation (Figs. 2A, 3 and 5A1, A2) and consists of very fine to very coarse medium-bedded/graded sandstones, medium/thick-bedded slightly muddy sandstones and structureless sandstones (decimetre- to metre-thick) (F6, F7, F8). F6 has normal to reverse graded sandstones, traction sedimentation structures such as cross-stratification, planar (Fig. 6H), asymmetrical and climbing ripple lamination (Fig. 6I). Normally graded slightly muddy very fine to fine sandstones with frequent asymmetrical ripples, planar and some convolute laminae develop within F7. Normally graded, amalgamated, structureless sandstones characterize F8 (Fig. 6I–K). The sandstone bases can be flat to erosional or with load casts (isolated load balls; F8; Fig. 6I) and flames. Mudstone rip-up clasts are frequent, and rarely can reach 80 cm on the long axis (F8; Fig. 6J). Thin F2 beds can be interbedded between F8-type sandstones (Fig. 6K). Centimetre-thick lenses of coarse/very coarse sand and scattered granules (locally imbricated – (a[p]a[i])) develop in some sandstones (F8, F6). The conglomerates can be sandy to clast-supported (F9; Fig. 6L) or can appear as disorganized muddy sandy conglomerates (F10; Fig. 6M). The conglomerates can be structureless (F10) and/or reverse to normally graded (F9; Fig. 6N) with flat to erosional bases (mudstone rip-up clasts). They have a grain size ranging from fine pebbles to large cobbles and rare boulders (limestones). A few breccias were observed in F9. Deformed mudstone- sandstone couplets charac-

Description and interpretation of the facies from Pucioasa section

Facies		Primary sedimentary structures/Bed thickness	Other features	Processes, depositional environment	Figure
Thin bedded sandstones	F1	1–10 cm grey vf/f sandstones (frequent 1–5 cm) between 2–50 cm thick mudstones. Ripples and climbing ripples, convolute lamination, load casts, rare faint planar laminations, often normal grading. Flutes to sharp bases. Muddy foresets. Rippled sandstones can evolve laterally, upward in convoluted sandstone.	Siltstones and vf sandstone laminae (ripples). Frequent phytodetritus. Rare small scale synsedimentary faults. Micas, sulphur, oxides in sandstones.	Low density turbidity flows (Tce, Tde, Tcde, Tbce) (Bouma, 1962; Talling et al., 2012). Traction sedimentation, excess pore pressure/rapid sedimentation (Mulder and Alexander, 2001; Talling et al., 2012). Distal levee/overbank setting of a channel (Hubbard et al., 2009; Fongngern et al., 2018).	6A–C
Massive, laminated, graded mudstones	F2	Structureless, planar parallel lamination to discontinuous/faint lamination (mm coarse silt laminas) in mudstones. Cm to m in thickness.	Dark/light grey, rare brownish/greenish coloured calcareous mudstones. Black organic rich laminae. Locally, organic matter is high but not like in F12. Silt content in mudstones can vary (normal/reverse graded). Phytodetritus (can be coalified). Pyrite, micas.	Hemipelagites, pelagites, diluted low density turbidity flows (Te, Tde) (Bouma, 1962; Talling et al., 2012). Some depostis could be related to muddy hyperpycnal flows of extrabasinal turbidites (Zavala and Arcuri 2016).	6D
Medium bedded muddy sandstones	F3	20–60 cm very fine/fine muddy sandstones. Frequent convoluted laminations, water escape structures. Flat to erosional sandstone base.	Phytodetritus, micas.	Slurry deposits (Lowe and Guy, 2000). Fan fringes, overbank crevasse splay lobes (Hubbard et al., 2009).	6E
Medium to thick bedded sandstones	F4	10–80 cm f sandstones, normal graded and amalgamated. Erosional/sharp base. Rippled, convoluted and planar laminated sandstones. Rare <3 cm thick bended muddy sandstones with ripples/convoluted lamination intercalations exists. Rare planar lamination made from coalified phytodetritus.	Cm thick lenses of c/vc sand grains. Phytodetritus, micas.	High density to low density turbidity flows (Tabce, Tbc, Tc; Bouma, 1962). Hindered settling, traction sedimentation (Mulder and Alexander 2001; Talling et al., 2012). Convoluted beds probably due to rapid sedimentation/excess pore pressure (Owen & Moretti 2011; Talling et al., 2012). Probably lofting deposits/hyperpycnal flows (Zavala and Arcuri, 2016). Fan fringes, overbank crevasse splay lobes (Hubbard et al., 2009).	6B, F

Tabl. 1 cont.

Facies		Primary sedimentary structures/Bed thickness	Other features	Processes, depositional environment	Figure
Centimetre to metre thick fluidized sandstones, fine conglomerates	F5	Structureless. Cm to m thick deposits.	Discordant with the host rock (dykes). Sills (undulating tops) and composite sill-dyke. Abrupt lateral terminations, chaotic intrusion swarms (host rock inclusions). Some injectites develop along fractures. Sandy fine conglomerates were observed.	Formed by overpressured and fluidized sandstones, sandy fine conglomerates intruded in background rocks (Duranti and Hurst, 2004) as injectites.	6B, G
Medium bedded graded sandstones	F6	30–60 cm normal graded, reverse to normal graded vf/f sandstones. Can stack >3 m in thickness. Planar lamination, cross stratification, asymmetrical climbing ripples and ripples. The last two can evolve laterally in convolute laminations.	Rare vf granuley sandstones (± pebbles) at the base of sandstones. Cm thick lenses of c/vc sand grains/scattered granules in sandstones. Sheared flames, load casts. Amalgamated sandstones, dish structures. Phytodetritus, micas.	Traction, traction carpets, rapid fall out sedimentation (S1, S2, S3/Ta) related to high density turbidity currents (Lowe, 1982; Talling et al., 2012) to low density turbidity currents (Tbc; Bouma, 1962). Channel fills in Fusaru/Slon formations. In Slon Formation, formed by filling/overflow of the negative/positive topography of the MTC	6H, I
Medium to thick bedded slightly muddy sandstones	F7	20–120 cm vf/f sandstones (frequent 20–50 cm) with some amount of muddy matrix. Normal graded, frequent asymmetrical ripples and planar lamination.	Amalgamated. Bioclasts. Rare convolute lamination. Phytodetritus, micas.	High/low density turbidity deposits (Ta, Tabc, Bouma, 1962; Talling et al., 2012), (?)slurry deposits (Lowe and Guy, 2000). Confined (Sprague et al., 2005) channel fills elements in Fusaru Formation.	
Medium to thick bedded structureless sandstones.	F8	40–100 cm that stack up to maximum 15 m in thickness. f to vc sandstones. Normal graded to no grading. Structureless. Often amalgamated. Dish structures. Flat to erosional base. Load casts (+isolated load balls).	Mudstones rip up clasts (<80 cm in size). Cm thick lenses of c/vc sand grains/ scattered granules. Alternating with F2 (rare). Rare cm/dm thick rippled, convoluted stack f sandstones toward the top. Muddy foresets. Phytodetritus. Sheared flames, micas.	S3 type sandstones (Lowe, 1982) formed by rapid sedimentation related to a high density turbidity flow followed (rare) by low density turbidity currents (Tc; Bouma, 1962). Confined (Sprague et al., 2005) fills in Fusaru Formation.	6I, J, K
Clast supported - sandy conglomerates/ breccia	F9	Structureless, reverse to normal graded. Dm thick that can stack >3 m in thickness. Flat, erosional base. Granules to very rare boulders (some limestones).	Micas, bioclasts.	Traction carpet and traction sedimentation related to high density turbidity currents (R2, R3; Lowe, 1982). Confined channel fills (Sprague et al. 2005) in Fusaru Formation.	6L, N

Tabl. 1 cont.

Facies		Primary sedimentary structures/Bed thickness	Other features	Processes, depositional environment	Figure
Disorganized muddy sandy conglomerates	F10	Structureless, rare grading. Dm/m thick beds. Grain size of conglomerates: up to 25 cm.	Mud clasts of various grain size (granulles to pebble). Micas.	*En masse* cohesive freezing of debris flows (Dm2 of Talling et al., 2012). Confined channel fills (Sprague et al., 2005) in Fusaru Formation.	6M
Slumped mudstones-sandstones couplets	F11	None in place. Metre in thickness	Faulting with some synkinematic sedimentation. F7 type sandstones. Onlap strata terminations. Rich in phytodetritus.	Levee slump failure. Related to the confined channel fills (Sprague et al., 2005) in Fusaru Formation.	6O
Organic rich shales (dysodiles)	F12	Structureless. Centimetre to metre in thickness.	Fissility. Coalified plant material (often), sulphur, gypsum efflorescence. F2, F13 intercalations appear around the base.	Hemipelagites, pelagites. Anoxic conditions due to palaeogeographic isolation (Amadori et al., 2012) with short term anoxic disruptions (F2 presence).	6P
Volcanic tuffs	F13	Massive, normal graded. Parallel laminated, asymmetrical ripples develop with dark muddy material on foresets. Convolute laminations. Cm/dm in thickness that stack up to <3 m in thickness.	Rare coal clasts, phytodetritus. Interbedded with F12.	Volcanic ash fall out reworked as diluted low density turbidity flows. Traction sedimentation. Ştefănescu et al. (1993) considered this type of tuffs in the ECBZ as deposited by bottom currents.	6Q
Chaotic m thick muddy sandstones and mud-clast conglomerates	F14	Structureless, chaotic bedding. Can stack >200 m in thickness. The thickness can be affected by reverse faults and covered intervals. One 2 m thick chaotic muddy vf sandstone bed.	Frequent cm thick organic rich shalestones (F12) clasts and cm to m thick greenish-reddish Cretaceous-Paleogene mudstones clasts. Interlayered around the base with m thick F12. Coal clasts, micas.	Caused by active compression tectonics that triggered mass failure of the upper slope/shelf edge that formed cohesive muddy debris avalanches/mass transport complexes (Moscardelli and Wood, 2008; Hubbard et al., 2009; Dm2 of Talling et al., 2012). *En masse* cohesive freezing (Lowe 1982; Mulder and Alexander, 2001). Deposited on the base of slope/basin floor (foredeep or wedge top basins). The F12 intercalation, can be an olistolite or structural repetition.	6R

terize F11 (Fig. 6O) that contain mostly F7-type sandstones. Onlap wedge strata terminations were identified in F11 at ~330 m (Figs. 5A1 and 6O). Structureless sandstones and sandy granules were seen injected (F5) into background mudrocks as dykes, forming intrusion swarms and abrupt lateral terminations. An interesting feature is some horizontal/sub-horizontal beds of F6, F7 with onlap terminations on erosional surfaces, at around 0–50 m (Figs. 5A1 and 8). These appear as organized lateral stacking (Funk et al., 2012) architectures (Fig. 8), migrating from south to north, locally with thin F2-type margin drapes (McHargue et al., 2011). Here palaeoflow measurements from sandstone flutes show transport to the ESE (Fig. 5A1, B). The last two observations indicate a gross west to east flow. The lateral stacking packages have an overall coarsening-upwards trend (Fig. 5A1).

Interpretation: The facies described in FA2 was deposited by high- to low-density turbidity currents (F2, F6–F9; Fig. 6H–L, N), cohesive debris flows (Dm2 of Talling et al., 2012; F10; Fig. 6M), slumping (F11, Fig. 6O) and fluidized overpressured sandstones – injectites (F5). In the low-density turbidity deposits, traction sedimentation relates to Tb, Tc and in places with Td/Te (Bouma, 1962; F6–F8, F2). The high-density turbidity deposits are interpreted as R2/R3 sequences of Lowe (1982) (F9; Fig. 6L, N) for conglomerates, deposited as traction carpets with rapid fallout sedimentation. For sandstones, S1–S3/Ta sequences (Bouma, 1962; Lowe 1982), (F6–F8; Fig. 6H–K) were interpreted as deposited by traction, traction carpets and suspension sedimentation. Cohesive debris flows (F10; Fig. 6M) were deposited through en-masse cohesive freezing (Talling et al., 2012). F11 (Fig. 6O) with deformed strata and synkinematic sedimentation (onlap/wedge) related to a slump failure on a levee made from F7/F2. We interpret FA2 of the Fusaru Formation as confined channel deposits (Sprague et al., 2005; Figs. 5A1, A2 and 7). The horizontal/sub-horizontal (Fig. 8B) beds between erosional surfaces (Fig. 8C–E) are typical of cut-and-fill geometries related to channel avulsion (Abreu et al., 2003).

FACIES ASSOCIATION 3 (FA3):
ORGANIC-RICH SHALES WITH MUDSTONES AND VOLCANIC TUFFS

FA3 describes the Starchiojd Formation with the Bătrâni Tuff (Figs. 2A, 3 and 5A1). F12 is composed of organic-rich fissile shales (dysodiles; Fig. 6P) with coalified phytodetritus, sulphur, gypsum efflorescences and some F2 mudstone interbeds. Also, two decimetre-/metre-thick grey-whitish, sometimes with reddish-brown coloured crusts, volcanic argillized plastic tuff packages (F13; Fig. 6Q) are developed, separated by 4-m-thick dysodiles. The tuff can be normal graded, massive or with planar, asymmetrical ripple and convolute laminae, interbedded with thin F12 rocks. Dark muddy material develops on the foresets of the asymmetrical ripple laminae (Fig. 6Q). The palaeocurrent flow (no dip correction) of the asymmetrical ripple laminae shows a trend to the SW.

Interpretation: The dysodiles were formed due to anoxic conditions related to basin palaeogeographic isolation (Amadori et al., 2012). These deposits were considered by Ştefănescu et al. (1993) to be a regional marker that drapes the older rocks (Fig. 7E). Brief anoxic disruptions are signaled by the presence of F2-type rocks (Fig. 5A1). The volcanic tuffs were deposited by low-density turbidity currents, given the numerous asymmetrical ripple laminae. Ştefănescu et al. (1993) interpreted some lower Miocene tuffs with asymmetrical ripple laminae from the ECBZ as deposited by marine bottom currents.

FACIES ASSOCIATION 4 (FA4):
CHAOTIC MUDDY CONGLOMERATES WITH ORGANIZED SANDSTONES

This characterizes the Slon Formation (Figs. 2A, 3 and 5A1) and consists mostly of structureless/disorganized muddy conglomerates (F14; Fig. 5A1). Centimetre-thick dysodile clasts and centimetre- to metre-thick greenish-reddish (Fig. 6R) mud clasts, originating from the nappes immediately to the north, were observed in a grey mudstone matrix. Around the base (~625 m – Fig. 5A1) interbedded non-chaotic metre-thick organic-rich dysodiles (F12) are present. F6-type metre-thick amalgamated normally graded sandstones with mud rip-up clasts, pebbles, asymmetrical ripple laminae and phytodetritus were identified near the top.

Interpretation: The F4 deposits were interpreted as mass transport complexes (MTC; Moscardelli and Wood, 2008) related to active compression tectonics (hinterland nappe stacking) that triggered mass failure of the upper slope/shelf edge (Fongngern et al., 2018; Fig. 7D, E). This formed cohesive muddy debris avalanches (Hubbard et al., 2009; Dm2 of Talling et al., 2012) that settled through en masse cohesive freezing (Lowe,1982, Mulder and Alexander, 2001). They were deposited around the base of the slope/basin floor (foredeep or wedge-top basins). The organized sandstones (F6) were deposited by high/low turbidity currents (Tac; Bouma, 1962) probably by filling the negative topography of (ponding in) the mass transport complexes. The metre-thick F12 may be a slide block (olistolith) from FA3, the result of in situ sedimentation disrupted by mass transport complexes, or a structural repetition. Due to poor exposure, interpretation is difficult.

BIOSTRATIGRAPHY

CALCAREOUS NANNOPLANKTON

The calcareous nannoplankton assemblages (Table 2) are characterized by a low to low/medium diversity, fluctuating abundance, and poor to moderate preservation. Due to the structural settings and sedimentation that can involve significant solids reworking, the identification of certain biozones was locally difficult. From the Diaconeşti–Vulcana Băi Anticline with Pucioasa Formation deposits (Ştefănescu et al., 1988) 16 samples were collected (PN1–PN11, PN16–PN20) and two logs were constructed (Fig. 5A3, A4).

The northern limb samples (PN1–PN11; Fig. 5A3) of this anticline are of moderate abundance and preservation and low/moderate diversity. Here, *Helicosphaera ampliaperta* (Fig. 9A) was identified in four samples (Table 2). As this species has its first occurrence within the NN2 Biozone (base Burdigalian; Mărunţeanu, 1999; Raffi et al., 2020) we interpret log 3 (Fig. 5A3) from the Pucioasa Formation as not older than Burdigalian (NN2 Biozone).

The southern limb of the Diaconeşti–Vulcana Băi Anticline (PN16-PN20; Fig. 5A4) is characterized by low abundance and diversity (Table 2) and poor preservation of the calcareous nannoplankton compared to the northern limb (Fig. 5A3). The first occurrence of *Helicosphaera scissura* (Fig. 9B) and *Reticulofenestra pseudoumbilicus* (<7 µm) (Fig. 9C) in the Paratethys were recorded in the NN1 Biozone and respectively at the base of the NN2 Biozone of the Aquitanian (Mărunţeanu, 1999; Melinte and Brustur, 2008; Kováč et al., 2017; Raffi et al., 2020). Young et al., (2017) proposed the first occurrence of *R. pseudoumbilicus* in the NN4 Biozone and the first occurrence of *Helicosphaera scissura* in the upper part of the NN2 Biozone. Therefore, we interpret log A4 (Fig. 5A4) of the Pucioasa For-
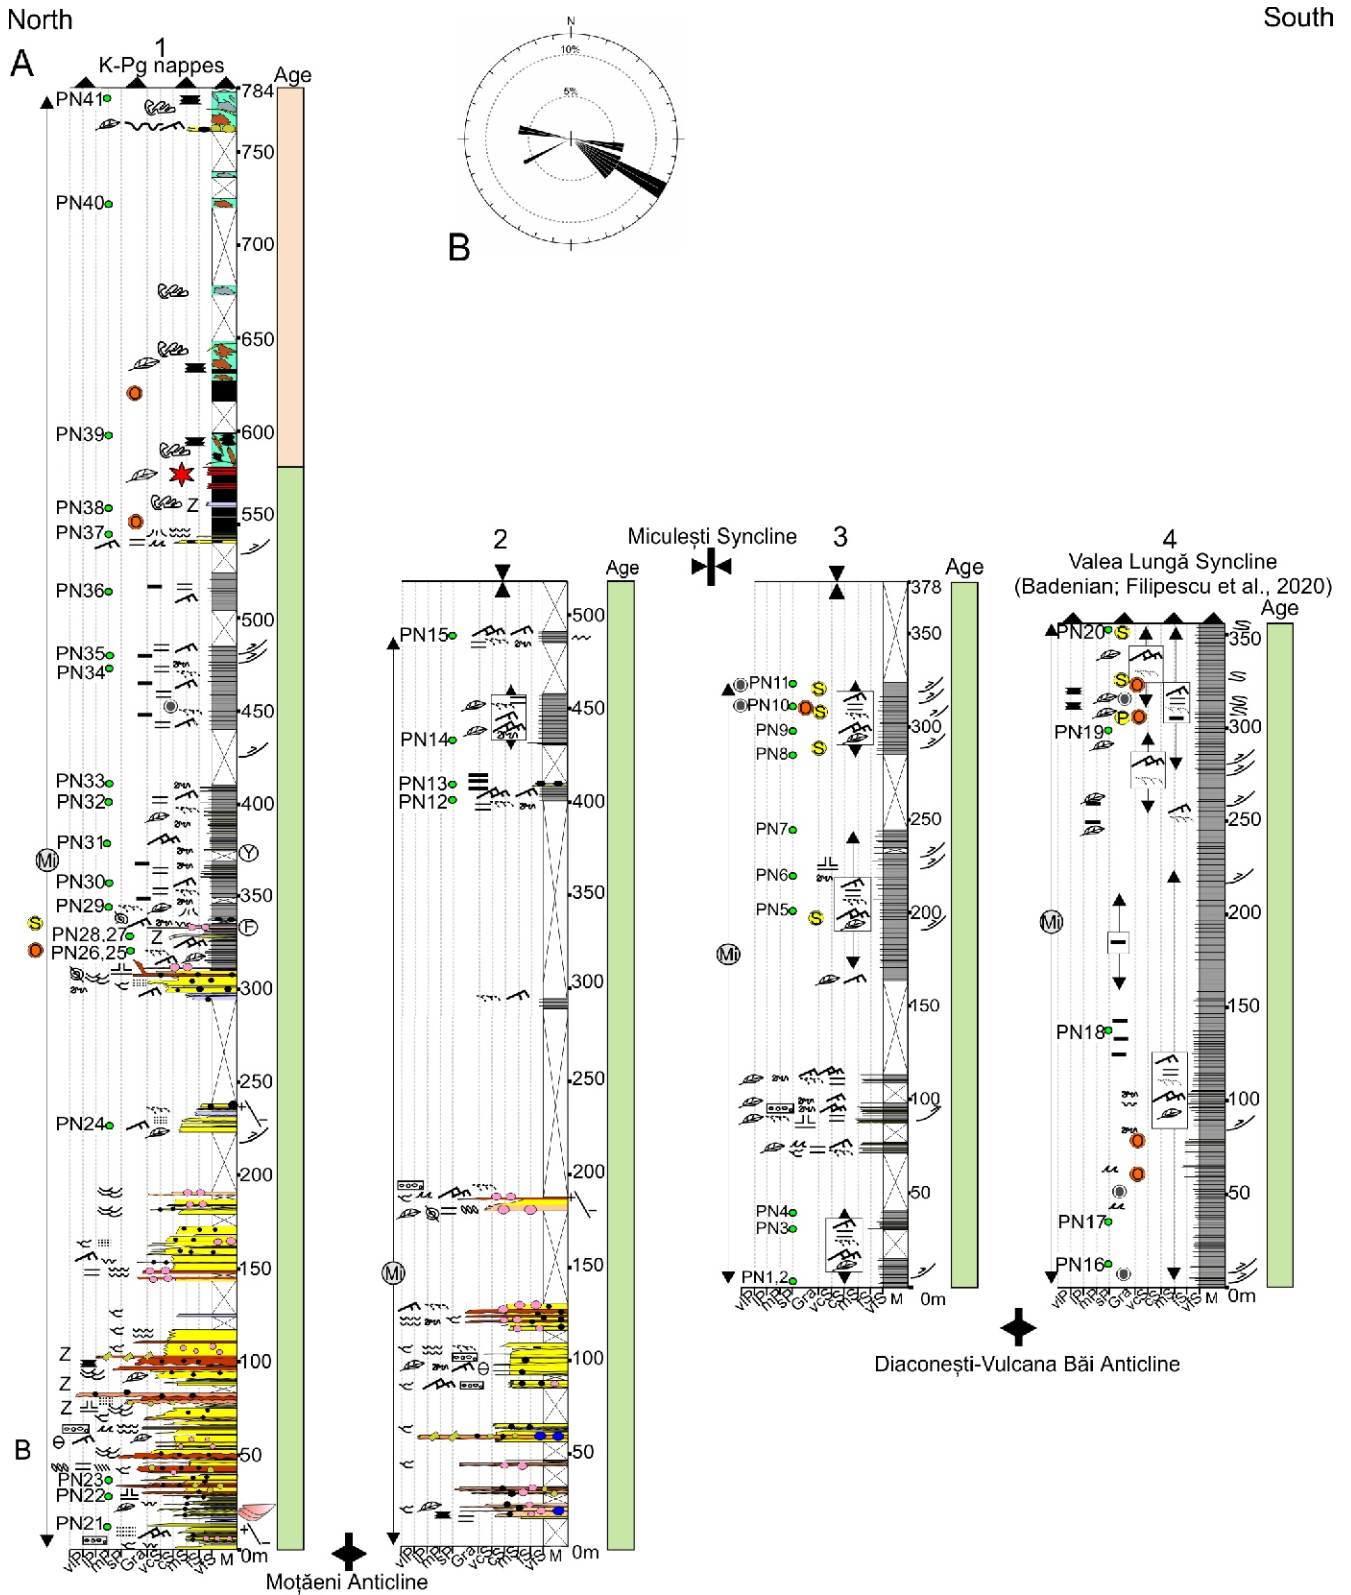

Fig. 5A – synthetic logs (1, 2, 3, 4) of the Bizdidel Valley showing the U/Pb and calcareous nannoplankton samples (see text for more details); B – some palaeocurrent measurements from Fusaru Formation sandstones (flutes and groove marks) – location log 1 base

vlP – very large pebbles, lP – large pebbles, mP – medium pebbles, sP – small pebbles, Gra – granulles, vcS – very coarse sands, cS – coarse sand, mS – medium sand, fS – fine sand, vfS – very fine sand, M – mudstone

mation as not older than Aquitanian (NN2 Biozone). Log 2 (Fig. 5A2) is situated in the southern limb of the Moţăeni Anticline (PN12–PN15) and was sampled only from mudstones of the Pucioasa Formation (Ştefănescu et al., 1988). It shows low/medium abundance, preservation and diversity (Table 2). *Helicosphaera ampliaperta* appears in all the samples investigated, and *Sphenolithus heteromorphus* (Fig. 9D,E) and *Helicosphaera walbersdorfensis* only in one sample (PN14). The first occurrence for the last two species noted is placed around the base of the NN4 Biozone (Young et al., 2017; Boesiger et al., 2017), although in the Paratethys realm *Helicosphaera walbersdorfensis* has been recorded from the upper part of the NN4 Biozone (Hohenegger et al., 2009) or higher , perhaps even in the NN6 Biozone (Mărunţeanu, 1999). Based on the co-occurrence of *Helicosphaera ampliaperta*, *Sphenolithus heteromorphus* and *Helicosphaera walbersdorfensis* and the closeness of the samples, we interpret log 2 (Fig. 5A2) of Pucioasa Formation as not older than Burdigalian (NN4 Biozone).

In the northern limb of the Moţăeni Anticline, 8 samples (PN21–PN28; Fig. 5A1) were taken from the mudstones found in the Fusaru Formation. These are of It has a low/moderate diversity and high abundance. *Sphenolithus belemnos* was identified in one sample (PN28) while *Helicosphaera ampliaperta* was observed in 4 samples (Table 2). *Sphenolithus belemnos* was identified within NN3 Biozone (Mărunţeanu, 1999) or in the upper part of the NN2 Biozone (Raffi, 2020). For this exposure an age not older than Burdigalian (NN2–NN3 Biozones) was interpreted.

The mudstones of the Vineţişu Formation (Fig. 5A1) showed a high abundance and low/medium diversity of species. Here, a more consistent appearance of *Helicosphaera ampliaperta* was observed (7 samples) together with a few specimens of *Helicosphaera walbersdorfensis* (PN30, PN34; Fig. 9F). Thus, based on the co-occurrence of these species we interpret this section as not older than Burdigalian (NN4 Biozone). One sample (PN 38) was taken from the Starchiojd Formation but it proved to be barren. Three samples were taken from Slon Formation (PN39–PN41) and they contained a few Miocene species (*Reticulofenestra haqii, Reticulofenestra pseudoumbilicus*) together with some long-ranging taxa (*Coccolithus pelagicus, Sphenolithus moriformis, Discoaster deflandrei, Reticulofenestra bisecta*).
THE BIOSTRATIGRAPHIC RE-EVALUATION OF PUBLISHED CALCAREOUS NANNOPLANKTON

Even though the formations were interpreted as Oligocene and Oligo-Miocene on the 1:50,000 geological map of Ştefănescu et al. (1988; Fig. 2A and Table 3), the associated calcareous nannoplankton may be interpreted differently. The presence of *Helicosphaera ampliaperta* in the Fusaru and Pucioasa formations indicates a Burdigalian age (not older than NN2 Biozone). The occurrence of *Helicosphaera ampliaperta* and *Sphenolithus belemnos* in the Vineţişu Formation indicates a Burdigalian age (NN2–NN3 Biozones) while *Sphenolithus heteromorphus* was identified only in the Starchiojd Formation which indicates a Burdigalian age (NN4 Biozone).

FORAMINIFERAL BIOSTRATIGRAPHY

The small number of planktonic foraminifera in most of the samples investigated and their mixed ages suggest that the specimens may have been sorted during transport and reworking. Rare local abundances (close to PN31 to PN34 in the Vineţişu Formation and around PN24 in the Pucioasa Formation) may be associated with marine flooding events. Two types of planktonic foraminiferal assemblages were distinguished: i) those with small globigerinids (*Tenuitella, Globigerina* – e.g. around PN20) reflecting eutrophic conditions (Filipescu and Silye, 2008; Beldean et al., 2012) and ii) those with large globigerinids (*Trilobatus, Globoquadrina* – e.g. south of sample PN32) typical of oligotrophic conditions of transgressive intervals.

The presence of *Trilobatus quadrilobatus* (e.g. around sample PN29; first occurrence in the Aquitanian M1a Zone of Wade et al., 2011; Fig. 9G), *Trilobatus subsacculifer* (e.g. around sample PN29; first occurrence in the Aquitanian M1b Zone; Fig. 9H), *Globoquadrina dehiscens* (e.g. around sample PN29, PN31–PN32; first occurrence in the M1b Zone), and *Tenuitella*

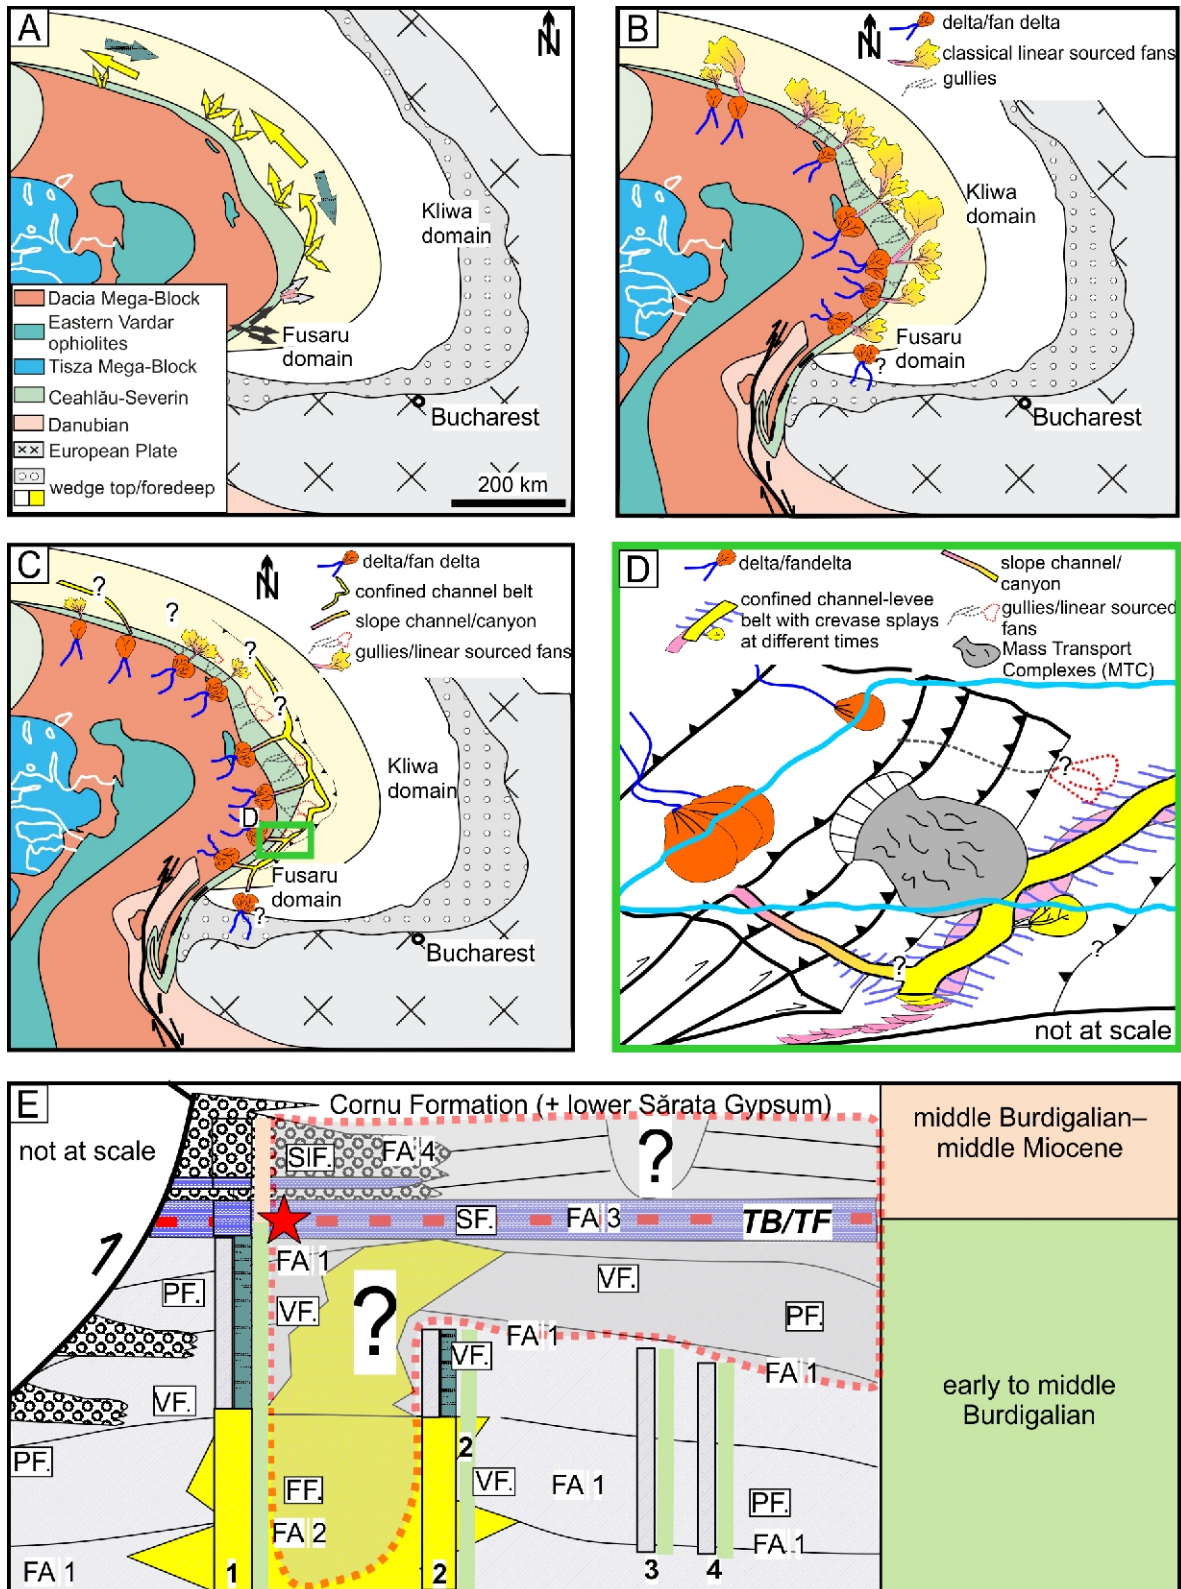

Fig. 7A – plotted palaeodirections on an early Miocene Carpathian foreland reconstruction (modified from Ustaszewski et al., 2008). Possible depositional environment interpretation: **B** – classical linear source gravitational flows – fan-shaped, that run approx. perpendicular to the basin axis; **C** – alternative interpretation with classical fans and a confined channels belt that run parallel to the orogen; **D** – close-up of the area of interest with continental/shallow marine sedimentation that feeds the confined channel-levee belt with crevasse-splay lobes. Also, large-scale Mass Transport Complexes were interpreted (see text for more details); **E** – hypothetical cross-section with the depositional environment interpretation based on logs and associated ages (PF. – Pucioasa Formation, VF. – Vineţişu Formation, PF. – Pucioasa Formation, SF. – Starchiojd Formation, SIF. – Slon Formation, FA.1 – Facies Association 1, TB/TF – Bătrani Tuff/Falcău Tuff). Red dotted light grey polygon represents the eroded area. Red star – U-Pb dated Bătrâni Tuff

clemenciae (e.g. around sample PN31–PN32; first occurrence in the Aquitanian M2 Zone) clearly demonstrate the Miocene age of the Vineţişu Formation. In the northern part of the section, corresponding to the Slon Formation (e.g. around sample PN40), the assemblage contains large planktonic foraminifera which were considered by Cicha et al. (1998) as ranging from the top of the early Miocene to mainly middle Miocene (Badenian): *Globigerina concinna, Globigerina diplostoma, Globigerinella regularis*. Other species, with larger ranges, but common in the Miocene, are present: *Globigerina bulloides, Globigerinella obesa, Globigerinita uvula, Globoturborotalita ouachitaensis* and *Tuborotalia quinqueloba*.

Although without specific biostratigraphic value, the calcareous benthic foraminifera from the dark grey mudstones of the Pucioasa Formation (Szabo, 2012; Fig. 3; samples PN20 to PN30) are of palaeoenvironmental importance. These are characteristic of outer neritic to bathyal settings (Culver, 1988; Leckie and Olson, 2003; Gooday and Jorissen, 2012), adapted to dysoxic conditions (*Brizalina alata, Br. pygmaea, Bolivina dilatata, Bol. molassica, Bol. liebusi, Bulimina elongata, Cassidulina margareta, Fursenkoina acuta, Globocassidulina oblonga, Nonionella stella, Oridorsalis umbonatus, Praeglobobulimina ovata, Pullenia bulloides, Valvulineria complanata, Virgulinella pertusa* etc.) or sometimes reflect oxic conditions on the substrate (*Amphimorphina hauerina, Elphidium grilli, E. hauerinum, E. reussi, Heterolepa dutemplei, Melonis pompilioides, Nodosaria elegantissima, Nonion commune* etc.).

PETROGRAPHY, ZIRCON U-Pb DATING AND TRACE ELEMENT COMPOSITION OF THE BĂTRÂNI TUFF

The Bătrâni Tuff is a fine-grained tuff within the Starchiojd Formation with up to 15–20% plagioclase, quartz and biotite of magmatic origin (Fig. 10A), the crystals of which are euhedral-subhedral, some being broken, with a narrow size distribution of 200–250 μm. The crystals are embedded in an altered (mostly argillitized) matrix that includes fossil moulds (Fig. 10A). The heavy minerals separated from the tuff are dominated by biotite, followed by zircon, apatite and ilmenite as magmatic crystals. The minerals suggest only minor reworking: zircon, apatite and phenocrysts have mostly euhedral or broken forms with no apparent chemical or mechanical abrasion; biotite is mostly fresh. The zircon grains have well developed magmatic zoning in cathodoluminescence images (Fig. 10B and Appendix 3). Data of *in situ* U-Pb dating is given in the Appendix 1.

We analysed 69 zircon crystal rim and 2 interior spots from which 61 give concordant results. A few spot analyses give older dates (interior: ~51 Ma, rims: ~189 Ma, ~240 Ma) whereas all others are Miocene. Two spot dates were excluded because of their high uncertainty. The 56 concordant Miocene dates range between 18.67 ±0.42 Ma and 17.09 ±0.27 Ma and they have a weighted mean age of 17.60 ±0.08 Ma with a Mean Squared Weighted Deviation (MSWD) value of 3.9 and three older outliers above 2 sigma uncertainty. The relatively high Mean Squared Weighted Deviation suggests more than one age component within the dates measured, therefore we calculated the low Mean Squared Weighted Deviation weighted mean age of the youngest age population, which is interpreted as the youngest crystallization age of the zircons. The youngest population with a weighted mean age of 17.41 ±0.06/0.27 Ma (MSWD = 1.5) is given by 32 dates. Therefore, 17.41 ±0.27 Ma (uncertainty also includes external errors) can be regarded as the closest age to the volcanic eruption represented by the zircon crystals. For the chemical characterization of the latest zircon crystallization domains we used the rim spots and excluded the relatively old and inclusion-contaminated data. Rim spots have 8250–10440 ppm Hf and 510–2727 ppm Y, Th/U ratio varies from 0.43 to 0.97 and U contents are between 384–1273 ppm. REE and Y contents show positive correlation with Th and U contents, while Hf shows negative correlation with Ti concentrations, which range between 1.5 and 6.8 ppm.

DISCUSSION

AGE INTERPRETATION

The biostratigraphy of the deposits studied needed reevaluation given the structural context and new radioisotopic age. As the interpreted age of the Bătrâni Tuff is 17.41 ±0.27 Ma, this regional lithological marker of the Starchiojd Formation (Ştefănescu et al., 1993; Figs. 3 and 5A1) must be placed in the middle Burdigalian (*sensu* Raffi et al., 2020).

The interval between samples PN21 and PN41 (Fig. 5A1) from the Fusaru and Slon formations (northern limb of the Moţăeni Anticline) represents the most continuous exposure (lithostratigraphically and chronologically) the section studied, ranging from the Burdigalian (NN2–NN4 Biozones) to middle Miocene, prior to the deposition of the middle Miocene Cornu Formation (Filipescu et al., 2020; Figs. 2A and 5A1). In the southern section, in the Miculeşti Syncline (Fig. 2A, B), the northern limb (Fig. 5A2) falls within the NN4 Biozone (correlating with the middle part of log 1) whereas the southern limb (Fig. 5A3) (or northern limb of the Diaconeşti-Vulcana Băi Anticline) was interpreted as falling within the NN2 Biozone. As the northern limb of the Miculeşti Syncline falls within the NN4 Biozone, we consider the equivalent upper part of the southern Miculeşti Syncline limb to fall also within the NN4 Biozone. Due to exposure gaps that affected the thickness measurements and some reverse faults (Fig. 5A3), the exact thickness of the NN4 Biozone in log 3 is difficult to assess, but it may be above sample PN8. To the west, in the Miculeşti Syncline (Fig. 2A), the younger Vineţişu and Starchiojd formations occur, therefore the NN4 Biozone for both limbs of the Miculeşti syncline from Pucioasa can be inferred. Nevertheless, in the Miculeşti syncline of the Pucioasa section, Ştefănescu et al. (1988) noted only Pucioasa deposits (Fig. 2A) although convolute sandstones, typical of the Vineţişu Formation, were observed (Fig. 6C). Regarding log 4 (Fig. 5A4) in the southern limb of the Diaconeşti-Vulcana Băi Anticline, the structural rationale suggests that it should have an lower–middle Burdigalian age (NN2–NN4 Biozones). The deposits belonging to the Starchiojd/Slon formations were not observed in logs 2, 3 and 4 (Fig. 5A2–A4). This may be due to lateral facies termination (i.e. Slon Formation) and erosion (Fig. 7E). Our results show that the age of the formations investigated along the Pucioasa section are younger than previously thought. The Fusaru and Pucioasa formations were previously considered as Oligocene (Ştefănescu et al., 1988; Melinte and Brustur, 2008), and the Vineţişu Formation as uppermost Oligocene to lower Burdigalian (NN2 Biozone; Mărunţeanu, 1999; Melinte and Brustur, 2008). Here we have an age model of not older than early Burdigalian (NN2 Biozone) and not younger than middle Burdigalian (NN4 Biozone) for the three formations. Even if the Starchiojd and Slon formations were interpreted as lower Burdigalian (NN2 Biozone; Mărunţeanu, 1999) we can expect an age ranging from middle Burdigalian to middle Miocene.

Interestingly, even if the calcareous nannoplankton zonation used for the 1:50,000 map of Ştefănescu et al. (1988) shows younger ages for the investigated formations, older ages were still assigned (Table 3).

DEPOSITIONAL ENVIRONMENT INTERPRETATION

The four logs were arranged as they were mapped, from the anticline axial planes (Diaconeşti-Vulcana Băi, Moţăeni) outwards (Fig. 5A). This can be helpful in getting a better overview of the lateral sedimentary transition. We can interpret that the immediate southern Pucioasa Formation represents an overbank/levee sub environment (Fig. 5A3). It is difficult to deduce if this distributary channel – levee environment is part of a classical fan oriented perpendicularly to the basin axis (Posamentier and Walker, 2006; Fig. 7B) or an axial channel belt parallel to the basin (De Ruig and Hubbard, 2006; Fig. 7C). The measured palaeocurrents in the Fusaru Formation are to the ESE (Figs. 5B and 7A – pink arrows), similar to those measured in Pucioasa Formation (Conţescu et al., 1966; Fig. 7A – grey arrows) in the area. In the eastern part of the area investigated Conţescu et al. (1966) noted that the distance covered by

(PN1, PN2, PN10, PN11, PN38, PN40 and PN41 marked as "Sterile")

the coarse-grained longitudinal flow deposits of the Fusaru Formation was ~200–250 km. They considered that the flows started in the area of ECBZ between Ploeşti and Buzău (Figs. 1B and 7A) and went northwards parallel to the fold and thrust belt along what is today the Eastern Carpathians. This distance in present day configuration covers almost all of the Eastern Carpathians (Fig. 1B). West of the area investigated, in the Getic Depression (Fig. 1B), Fusaru-like slope coarse-grained siliciclastic deposits (Roban, 2008; Corbi and Cheia formations) were described as having a dominant SE-wards palaeocurrent direction (black arrows; Figs. 1B and 7A) by Jipa (1982, 1994 fide Roban, 2008). However, this could have fed some older Fusaru Formation, that now lies at depth in the area investigated (Fig. 7C, D). As the formations from the study area are younger than previously interpreted, that constrast with the rest of the Getic – ECBZ – Eastern Carpathians stratigraphy, we consider that a regional study is necessary for age re-evaluation. Nevertheless, the existing palaeocurrent data can be used, as regardless of age it shows dominant eastwards/northwards longitudinal (Jipa, 1966) current flow. As the palaeoflow in the area of study is to the east, and appears to be parallel to the orogen, we consider the Pucioasa and Fusaru formations as part of an axial channel levee belt (Hubbard et al., 2008; Fig. 7D) that originated in the west (Getic Depression). It may have flowed north-eastwards, eastwards (Fig. 7A) and perhaps continued towards the Eastern Carpathians. Probably it was also fed by transverse flows from the hinterland (Hubbard et al., 2008) coexisting with classical transverse fan environments (Conţescu et al., 1966; Jipa, 1966; Fig. 7C). It is difficult to say whether the axial channel levee belt was continuous for hundreds of kilometres and extended across all of the Eastern Carpathians or whether was discontinuous. The characteristic convolute sandstones of the Vineţişu Formation present in the lower and middle part of log 1 disappear upwards (Figs. 2A, 5A1 and 7E) into beds characteristic of the Pucioasa Formation. Also, in the northern limb of the Miculeşti Syncline, many convolute sandstones developed in what was interpreted as Pucioasa Formation (Ştefănescu et al., 1988). These sandstones may be equivalent to the convolute sandstones from the lower-middle part of the Vineţişu Formation in log 1. We interpret the Fusaru channels as having migrated laterally (Fig. 7E), for instance between the areas of log 1 and log 2 (eroded today). Therefore, the Vineţişu and Pucioasa formations are lateral equivalents, related to a channel overbank/levee sub-environment where the Pucioasa Formation was distal in relation to the Vineţişu Formation. Only 3 qualitative palaeoflow measurements were made for some asymmetrical ripples around samples PN29–PN30 and these have a roughly eastwards direction (no bed tilt correction). Conţescu et al. (1966) plotted some south and south-west palaeoflows (green arrows; Figs. 1B and 7A) for the Vineţişu Formation (in the Eastern Carpathians area) but did not record from where in the formation the measurements were taken. The only west-

wards-directed palaeoflows observed (no tectonic tilt correction) relate to ripples from the Bătrâni Tuff within the restricted Starchiojd Formation (Fig. 6Q). Ştefănescu et al. (1993) considered the lower Miocene tuffs of the ECBZ as deposited by bottom currents. As the compression migrated in a foreland direction, the Fusaru channels and associated formations migrated laterally (Fig. 7E). This can be seen through the presence of the very thick Slon Formation (Fig. 5A1) related to the active compressional tectonics. This facies is diachronous (Ştefănescu et al., 1988; Răbăgia et al., 2011) given its presence elsewhere within the Vineţişu and Cornu formations (Olteanu, 1952; Ştefănescu, 1995) and probably follows the movement of the thrusts. Similar synkinematic deposits have been documented in the Ukrainian Carpathians (Hnylko, 2014). The ~100-m-thick massive to convolute sandstones with fine conglomerates described by Ştefănescu (1995) somewhere towards the hinterland should not be interpreted as Slon Formation as the latter is a cohesive debrite while the sandstones relate to high-density gravitational flows. As the younger shallow marine piggyback deposits of the Valea Lungă Syncline are considered middle Miocene (Bercea et al., 2016; Filipescu et al., 2020; Figs. 2A,B and 5A4), then at the time of deposition of the deep marine exposures investigated, the lateral shallow marine equivalent was situated somewhere towards the hinterland.

ORIGIN OF THE BĂTRÂNI TUFF

Early Miocene silicic pyroclastic rocks and volcanic ash-bearing strata are known at many localities in the Carpathian-Pannonian region and also in its surroundings as both proximal and distal facies (e.g., Alexandrescu et al., 1981, 1994; Ştefănescu et al., 1993; Szakács et al., 2012; de Leeuw et al., 2013; Lukács et al., 2015, 2018, 2021; Rocholl et al., 2018; Rybár et al., 2019; Brlek et al., 2020; Sant et al., 2020; Danisik et al., 2021; Šarinová et al., 2021). The distal pyroclastic intercalations (usually tuffs) have a great importance not only in dating sedimentary sections, but also in revealing the nature of the silicic explosive volcanic activity (areal coverage, volume and explosivity) of that time. Lukács et al. (2018) identified four main early Miocene ignimbrite-forming explosive eruptions in the Bükkalja Volcanic Field, northern Hungary; these are the Csv-2 ignimbrite at 18.2 ±0.3 Ma, the Eger ignimbrite at 17.5 ±0.3 Ma, the Mangó ignimbrite at 17.065 ±0.014 Ma and the Bogács ignimbrite at 16.816 ±0.059 Ma. Recently, Karátson et al. (2022) and Brlek et al. (2023) refined the age of the Eger eruption event to 17.3 Ma and the Csv-2 (named as Wind/Kalnik) eruption to 18.1 Ma with <100 ky uncertainties. The thick Bătrâni Tuff from the ECBZ represents the product of one such eruption, which provides indication of a possible large explosive volcanic event. It was correlated by Frunzescu (2013), based on lithostratigraphy, with the Falcău Tuff (Alexandrescu et al., 1981) of the Eastern Carpathians

Table 3

Reinterpreted calcareous nannoplankton from Ştefănescu et al. (1988)

Stratigraphy based on Ştefănescu et al. (1988)			Age reinterpretation based on calcareous nannoplankton	
Slon Formation	Starchiojd Formation	lower Miocene	*Sphenolithus heteromorphus*	not older than Burdigalian (NN4 Biozone)
	Vineţişu Formation	Oligo–lower Miocene	*Sphenolithus belemnos*	Burdigalian (NN3 Biozone)
Pucioasa and Fusaru formations		Oligocene	*Helicosphaera ampliaperta*	not older than Burdigalian (NN2 Biozone)
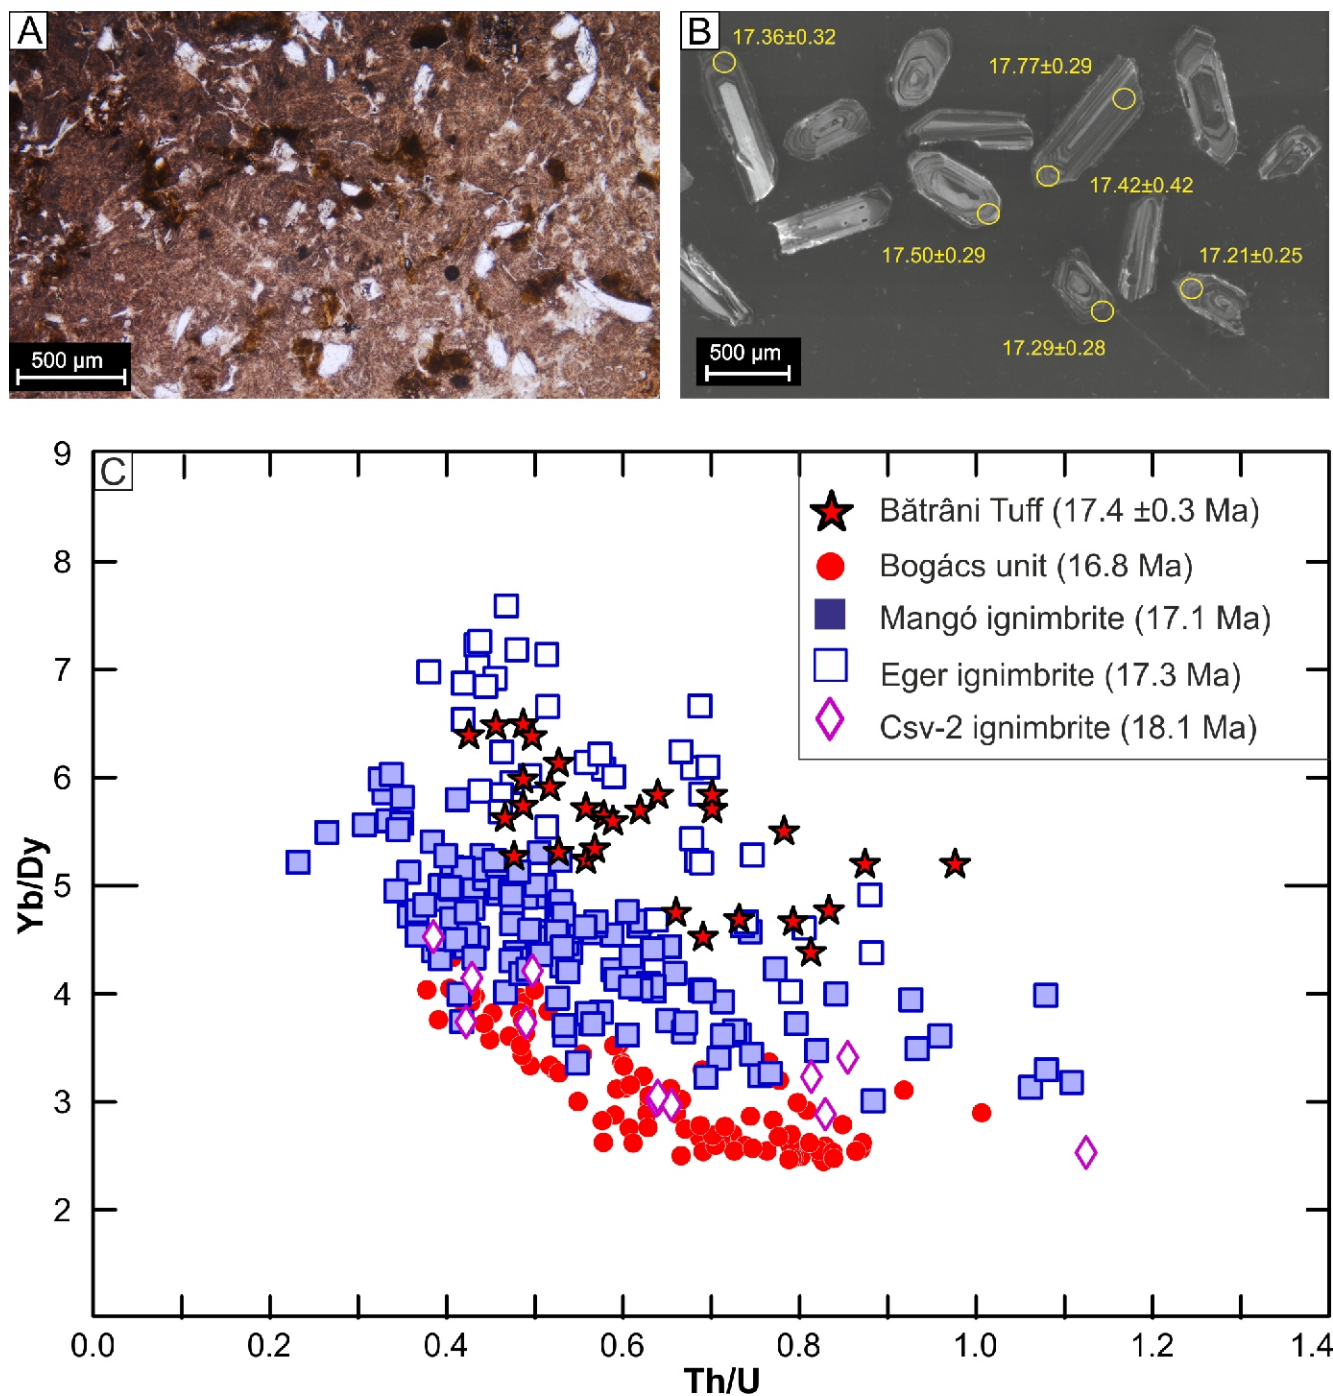

Fig. 10A – optical microscopic image (4x) of the Bătrâni Tuff showing angular crystals (feldspar, quartz, biotite), fossil fragments in altered matrix; **B** – cathodoluminescence images of zircon crystals separated from the tuff with spots (30 μm) of Laser Ablation Inductively Coupled Plasma Mass Spectrometry (LA-ICP-MS) analyses. Ages are in millions of years; **C** – zircon trace element ratios discriminating the lower Miocene main ignimbrite units of the Bükkalja Volcanic Field after Lukács et al. (2021). The Bătrâni Tuff zircons show similar trace element ratios to those of the Eger ignimbrite

(Fig. 3). The homogeneous grain (phenocryst) size distribution, mineral assemblage, the freshness and un-abraded character of the magmatic minerals of the Bătrâni Tuff sample studied suggest a rapid and relatively short re-sedimentation route, presumably by low-density turbidity currents/marine bottom currents after fall deposition. The source of the pyroclastic material can be inferred using combined geochronological and geochemical correlation (e.g., Lowe, 2011; Lowe et al., 2017; Pearce et al., 2020; Lukács et al., 2021; Prentice et al., 2022).

The age of the tuff within uncertainty can be correlated with the ~17.3 Ma Eger ignimbrite-forming eruption of the Bükkalja Volcanic Field. The Eger ignimbrite is a ~30 m thick silicic lapilli tuff proximally (i.e. in the Bükkalja Volcanic Field) with a similar main mineral assemblage (quartz, plagioclase, biotite). In the case of the Bătrâni Tuff studied, the juvenile glass fragments are not suitable for chemical characterization and correlation due to their severe alteration. Lukács et al. (2021) showed that zircon trace element compositions can be effectively used to

correlate the main pyroclastic units of the Bükkalja Volcanic Field (Fig. 1A) with their distal counterparts and suggested that this geochemical correlation technique could be powerful in case of altered pyroclastic deposits. In bivariate trace element and trace element ratio diagrams a striking similarity can be observed between the zircons of the Bătrâni Tuff and those of the Eger ignimbrite (Fig. 10C). The distinct chemical composition of the Eger ignimbrite zircons among the early Miocene ignimbrites of the Bükkalja Volcanic Field is best visualized on the Th/U versus Yb/Dy diagram (Lukács et al., 2021). Zircons of the Bătrâni Tuff have a high Yb/Dy ratio for a given Th/U ratio (Fig. 10C) as shown also by zircon crystals in the Eger ignimbrite of the Bükkalja Volcanic Field. They share this distinctive character among the early Miocene pyroclastic rocks (Fig. 10C). Thus, the similar phenocryst assemblage, zircon U-Pb age and zircon chemistry all suggest that the Bătrâni Tuff as a distal product of the 17.3 Ma Eger eruption.

The pyroclastic suite at Ipolytarnóc (North Hungary), ~75 km away from the proximal BVF deposit, also has a similar zircon U-Pb and ^{40}Ar/^{39}Ar age and zircon trace element composition to the Eger ignimbrite as shown by Lukács et al. (2021), Šarinová et al. (2021) and Karátson et al. (2022). Brlek et al. (2023) identified the Eger eruption-related ignimbrite in the Mt. Kalnik (Croatia) and fall deposits in the Sinj Basin (Croatia), based on zircon U-Pb dating, glass and zircon geochemistry. Possible distal counterparts of the Eger eruption were proposed by Lukács et al. (2018) west from the Pannonian basin, in the Northern Alpine Foreland. We propose here that the Bătrâni Tuff may be another distal deposit of this eruption event and the first example demonstrating that pyroclastic fall occurred also east-southeast of the Bükkalja Volcanic Field, the ash being deposited in a deep marine environment.

CONCLUSIONS

This integrated structural, sedimentological and biostratigraphic study, coupled with zircon U-Pb dating, provides better constraints on the age of the stratigraphic sequence investigated. The Pucioasa, Fusaru and Vineţişu formations have an early to middle Burdigalian age (NN2-NN4 biozones). The age of a regional lithological marker of the Starchiojd Formation was obtained by U-Pb dating of the Bătrâni Tuff, resulting in an age of 17.41 ±0.27 Ma, which falls within the middle Burdigalian. The re-interpretation of older calcareous nannoplankton data from Ştefănescu et al., (1988) also shows a Burdigalian age (NN2–NN4 Biozones).

The deposits studied are interpreted as a longitudinal stacked channels belt (Fusaru Formation) with associated levee/overbank (Pucioasa, Vineţişu formations) deposits which are lateral equivalents, sourced from the west. They migrated laterally as the compression propagated towards the foreland. This propagation can also be interpreted through the presence of the diachronous Mass Transport Complexes of the Slon Formation, which was formed through the collapse of the upper shelf due to hinterland nappe stacking. The Bătrâni Tuff in the ECBZ with its Eastern Carpathians correlative the Falcău Tuff (Frunzescu, 2013) may be a distal counterpart of one of the largest eruptions identified in the Bükkalja Volcanic Field, Hungary, based on their similar zircon U-Pb age and trace element composition. In this case, the Bătrâni Tuff is the first identified pyroclastic fall deposit of the 17.3 Ma Eger eruption event, several hundred kilometres east-southeastwards of the Bükkalja Volcanic Field.

The formations exposed in our study area were most likely subsequently deformed during the intra-Burdigalian/Badenian –Sarmatian and the Wallachian phases. The former is most likely associated with the earlier NNW–SSE-trending thrust, while the latter is associated with E–W to WSW–ENE-trending contractional structures. This later event is also associated with NNW-SSE-trending dextral faults (and associated Riedel shear structures) acting as tear faults which partitioned the deformation in the area.

Nevertheless, regional studies including source area analysis, more palaeocurrent data measurements integrated within a depositional environment interpretation and detailed structural analysis is required, in order to reach better understanding of the evolution of lateral depositional environments along this Carpathians internal foredeep/wedge top setting.

Abbreviations

Int – internal

Prop – propagated

Approx – approximate

CPS – counts per second

SE – standard error

s – second

logDose – logarithm of the alpha radiation dose, calculated as given in equations (1) in Sliwinski et al. (2017)

Reference

Sliwinski, J.T., Guillong, M., Liebske, C., Dunkl, I., Quadt, A.V., Bachmann, O, 2017. Improved accuracy of LA-ICP-MS U-Pb ages of Cenozoic zircons by alpha dose correction. Chemical Geology, **472:** 8–21.

Appendix 2
Zircon trace element analyses: background and data

Background for trace element analyses

Session	spot size	refernce material	masses measured (amu)	quality control refernce material	Internal Standard
Session 2021118_1b	30	NIST610	27, 28, 31, 49, 89, 91, 93, 138, 139, 140, 141, 146, 147, 153, 157, 159, 163, 165, 166, 169, 172, 175, 178, 181, 232, 238	91500, Synth Zircon Blank	Si, 15.2 wt%

Abbreviations

Ti (corr) ppm = Ti(measured in sample)/(average of Ti(measured in 91500))*4.73 (see details in Szymanowski et al., 2017)

Nb* = Nb(measured in sample) – (average Nb(measured in Synth Zirc Blank)

Eu/Eu* = (Eu/0.058)/(SQRT(Sm/0.153*Gd/0.2055))
